1 INTRODUCTION

Solid state NMR (SSNMR) is now established as a common method for answering questions about active-site chemistry in proteins. The technique has usually been applied to study insoluble proteins such as membrane proteins and structural proteins. In some cases chemical intermediates trapped at low temperatures have been studied. Recently there have been extraordinary advances in the development of SSNMR dipolar methods that are applicable to biological solids (reviewed elsewhere in this Encyclopedia). However, the majority of mechanistic problems solved with solid state NMR to date have relied on measurements of chemical shifts. In these studies, carbon, nitrogen or phosphorus spectra are measured using excitation by cross polarization from protons, and line-narrowing methods such as magic angle spinning and proton decoupling (CP MAS).^{1,2} Chemical shift measurements in proteins have usually been interpreted by comparison with the spectra of characterized 'model' compounds.

The anisotropy, or distribution of chemical shift values as a function of the spatial orientation of the sample in the magnetic field, can be measured in the solid state and is compactly summarized in the form of three values for three principal directions, δ_{11} , δ_{22} , and δ_{33} . These three values of the chemical shift anisotropy (CSA) are usually measured by simulation of the magic angle spinning spectra taken at low spinning speeds.^{3,4} For some of the protein work described here, the full CSA was reported but in the majority of cases only isotropic values were reported [which is equivalent to the centerband value: $\delta_{\text{iso}} \equiv \frac{1}{3}(\delta_{11} + \delta_{22} + \delta_{33})$]. There are a few important cases in which the chemical shift anisotropy tensor measured in the solid state gives more dramatic and unmistakable chemical trends than solution state measurements, especially for studies of ionization and hydrogen bonding, and we will highlight this point in the review.

In this review we attempt to emphasize examples of the kinds of problems that have been solved by solid

state NMR, and consequently the examples are organized by the general types of chemical topics rather than by aspects of the NMR methods, for example detection of covalent modification, conformational strain, or nonbonded interactions.

2 CHEMICAL SHIFTS: OVERVIEW AND REFERENCING

The typical range of ^{13}C and ^{15}N isotropic shifts and CSA values for most functional groups commonly found in proteins is indicated pictorially in Figure 1. A database of chemical shifts for characterized solids has been recently compiled,⁵ and this review includes anisotropic tensor values for a broad variety of chemical classes and nuclei. For the case of ^{13}C chemical shift anisotropy, there is an excellent older review

^{13}C chemical shift tensors of chemical classes in proteins

^{15}N chemical shift tensors of chemical classes in proteins

Notes: 1. This type of nitrogen includes:

2. This type of nitrogen includes:

within the same type, the chemical shielding values may vary ± 10 ppm

Figure 1 Typical ^{13}C and ^{15}N chemical shift tensors of interesting chemical classes typically found in proteins. Open squares represent CSA elements δ_{11} , δ_{22} , and δ_{33} , from left to right, respectively, and closed squares represent the isotropic chemical shift, δ_{iso} . The square around δ_{22} of the carbonyl group indicates the variation of that tensor element, which is caused by hydrogen bonding. A description of the spatial orientation of the CSA tensor for several carbons can be found in Veemun;⁶ for amides, see also Ando et al.⁷⁴ and Asakawa et al.;⁷⁵ for carboxy groups, Gu and McDermott⁶⁷ describe chemical trends and orientations. For the ^{15}N NMR of amides, Oas et al.⁶⁶ describe the orientations

of the typical values for various chemical classes and their associated spatial directions.⁶

In Figure 1, a general trend in increased anisotropy with increased deshielding is apparent, reflecting the spatial anisotropy of the low-lying molecular orbitals that induce large paramagnetic effects. When the CSA is less than ca. 2 kHz the anisotropic values are difficult to measure and are not reported, such as the case for ¹⁵N measurements of amines and many proton CSA measurements. We have throughout followed the nomenclature that $\delta_{11} > \delta_{22} > \delta_{33}$ in ppm where δ_{11} is the deshielded or higher frequency (downfield) element and $\delta_{\text{iso}} = \frac{1}{3}(\delta_{11} + \delta_{22} + \delta_{33})$. In many references alternative nomenclature is used. For example the labels δ_{xx} , δ_{yy} , and δ_{zz} are defined by the criterion $|\delta_{zz} - \delta_{\text{iso}}| > |\delta_{xx} - \delta_{\text{iso}}| > |\delta_{yy} - \delta_{\text{iso}}|$. The CSA is often described in terms of width and rhombicity. Commonly, δ , $\delta(\sigma)$, or the Hebrew letter Beth ($\beth$), refer to the spectral width defined as $\delta_{zz} - \delta_{\text{iso}}$, and the rhombicity or anisotropy, η , is defined as $(\delta_{yy} - \delta_{xx})/(\delta_{zz} - \delta_{\text{iso}})$. A less common nomenclature utilizes μ as a measure of the spectral width and ρ as a measure of rhombicity:

$$\mu = 2\pi\gamma H_0(\delta_{11} - \delta_{33})/\nu_r \quad \text{and} \\ \rho = (\delta_{33} + \delta_{11} - 2\delta_{22})/(\delta_{33} - \delta_{11}) \quad (1)$$

where γ is the gyromagnetic ratio, H_0 is the applied magnetic field and ν_r is the MAS spinning speed. When a uniaxial approximation is acceptable (as is frequently used in solution T_1 studies) $\Delta\sigma$ refers to the width defined as $\delta_{zz} - \frac{1}{2}(\delta_{xx} + \delta_{yy})$ and η is assumed to be zero.

Carbon spectra are generally referenced to tetramethylsilane (TMS) at 0 ppm; in practice the larger and more shielded of the two carbon peaks (the methylene peak) of adamantane is used experimentally and set to 38.6 ppm relative to TMS. Nitrogen spectra can be referenced to any of a number of compounds and in the absence of consistent literature adherence to the IUPAC standard (neat nitromethane), it is worthwhile to compare the various standards that are commonly used. Protein data in solution are usually referenced to liquid ammonia at -50°C as 0 ppm. In this article we will report all shifts on this scale, correcting from the references if necessary.

In Table 1 we list many of the common ¹⁵N references collected from several sources.^{5,7,8} [Note that several groups have used 1 M HNO₃ solution but reversed the normal direction of the scale, i.e. they indicate more shielded nitrogens with larger (positive) shift values.] Phosphorus-31 NMR spectra are referenced to 85% H₃PO₄.

A recent article reports the ¹³C chemical shift anisotropies of solid amino acids.⁹ It is of note that the practice of assigning the resonances on the basis of a comparison of the isotropic shifts measured in the solid state with the solution values has led to some errors: in particular the methyl assignments are generally ambiguous and there are clear errors in the γ -carbon of aspartic acid, the C-1 for Asn and Gln, as well as the terminal amides for both. Examination of all three tensor elements and comparison with previously determined tensors is usually a more reliable method for assignments if the group is known to be essentially static. When this is ambiguous, then a more definitive assignment is possible by selective labeling or more sophisticated editing and 2D methods.

Table 1 Nitrogen Chemical Shift References of Standard Compounds

Chemical shift standard	Chemical shift (ppm)
Liquid ammonia (-50°C)	0
Liquid ammonia (25°C)	-3.37
Amine of NH ₄ NO ₃ (aq.)	18.23 (1–10 M)
Amine of NH ₄ NO ₃ (saturated, 25°C)	17.31
NH ₄ Cl (1 M in 2 M HCl solution)	18.5
NH ₄ Cl (2.9 M in 1 M HCl solution)	21.56
NH ₄ Cl (1 M in 10 M HCl solution)	26.94
NH ₄ Cl (saturated solution, 5.6 M)	23.97
NH ₄ Cl (solid)	38.5
1 M HNO ₃	372.4
Nitromethane in CDCl ₃	
[1:1, 0.03 M Cr(acac) ₃]	376.23
Nitromethane (neat)	376.86

3 LINEWIDTHS AND GENERAL CONSIDERATIONS FOR SAMPLE PREPARATION

In general, solid state NMR measurements require specific introduction of a rare isotope, usually ¹⁵N or ¹³C, and this can at times present a practical limitation since the preparation of the appropriately labeled compounds can be an arduous task, especially because of the limited number of appropriately labeled starting materials that are commercially available in an inexpensive form. For this reason, the application of solid state methods is usually limited to situations of special interest, or where other methods have encountered some limitations. The label is most often introduced to an active site ligand or chemical modification agent, or by specific labeling of amino acids introduced into a protein in an overexpression system. The availability of appropriate model compounds can also be a limitation when the proposed chemistry at the enzyme active site is unusual and involves unstable compounds. So in at least two regards the recent progress in SSNMR has been directly dependent upon chemical synthetic efforts. For adequate sensitivity, in the case of CP MAS measurements it is necessary to have more than 0.1 μmol of spins and preferably 1 μmol when possible. One important exception is the spectroscopy of ‘high-gamma’ nuclei such as ¹⁹F, where the detection of 10 nmol is possible.

Since the molecular weight range is often discussed as a criterion for selecting solution versus solid state methods, we will attempt to identify some cases of interest regarding detection of signals from large proteins in the solution state. It is particularly notable that studies of high molecular weight proteins (280 kDa) in viscous solvents at low temperatures have given nice linewidths by solution NMR (vide infra),³⁴ so that when a protein is rather soluble it is worthwhile making a deliberate choice between solution and solid state methods. It is also noteworthy that several groups have characterized the NMR spectra of insoluble proteins, such as fragments of intrinsic membrane proteins, using solution NMR in organic solvents.^{76,77}

Carbon or nitrogen linewidths measured with CP MAS (~ 1 ppm) are typically much greater than in solution (≤ 0.2 ppm), and so many of the conformational effects that are reliably correlated with chemical shift in solution might be subtle in the solid state. Linewidths for solid state small molecules are usually strongly dependent upon both the crystallinity of the sample and on instrumental parameters such as the strength

and frequency of the proton decoupling or the adjustment of the magic angle. The linewidths of enzyme-bound species can depend very strongly upon details of the solid state enzyme preparation. Often lyophilized samples have rather broad lines, and it has been reported in one case that the rate of freezing is important in determining the linewidth and in another that the degree of hydration is very important.^{10a,b}

Preparation of frozen solutions has also had varied success; for this approach it is often necessary to lower the temperature well below 0°C to obtain a true solid in which cross polarization and other standard solid state techniques are successful. The internal mobility of the sample can have the effect of interfering with cross polarization or with line-narrowing methods. As a result, when motion on the μ s to ms timescale is present, signals can be weak or disappear entirely.⁷⁸ Simple hydrated pellets of membrane proteins normally give acceptable linewidths if the labeled ligand is in a well-defined binding pocket. These samples can sometimes be measured at room temperature, for example, if the sample consists of large fragments of intact membrane, but if their correlation times are too rapid, such as the case when excess detergent used in purification is present, then low temperatures must be used. Good quality spectra have been taken of microcrystals of enzymes. In many cases precipitants that preserve enzyme activity can be found, and enzymatic activity is normal even in the presence of precipitants such as polyethylene glycols.

4 COVALENT ADDUCTS AT THE ACTIVE SITE

Chemical shift analysis in the solid state often gives rather direct indication of covalent modification. Some of the exciting applications of this method involve active-site chemistry, either in the catalytic cycle or in mimics of the catalytic cycle. In rare situations actual kinetic intermediates can be detected by time-resolved low-temperature methods and solution NMR methods,^{11,12} and the same cases are likely candidates for stopped-flow and rapid freeze techniques with solid state NMR spectroscopy.¹³ An intermediate will build up to a large steady-state population in the special case that the rate for conversion from intermediate to product is slow in comparison with the rate at which it is generated. Such a situation is actually rather rare, since typically the intermediate is unstable and reactive when compared with the Michaelis complex. The lifetime must also be slow compared with the instrumental detection time and practical rates of sample manipulations (several ms). However, in special cases the intermediates are long-lived and detection is possible, such as the hemiketal formed on shikimate synthetase (discussed below).

The formation of a covalent (but unstable) intermediate in chemical catalysis is quite common and inhibitors are often fashioned on the principle of forming an analogous but more stable bond. These inhibited complexes can help delineate the scope of the chemistry of the active site, and normally they are considerably easier to detect than the intermediates of catalysis. Establishing these structures for the covalent adducts has often been of significance to pharmaceutical design efforts and has been difficult by other methods. The goal of the studies enumerated here has usually been to prove that inhibition *definitely* proceeds by a mechanism that is analogous to the *proposed* catalytic pathway. Numerous examples of inhibition

reactions at the active sites of enzymes have been studied by CP MAS. Although this kind of work has few general lessons, it is of impressive scope at this point in time.

A related class of applications of solid state NMR for the study of active-site compounds is the detection of bound-state products. While it is rare that either the Michaelis complex or a true intermediate can be kinetically trapped, it is quite common that the bound-state product can; such complexes are commonly studied by crystallography. A relatively early example of the application of SSNMR to mechanistic enzymology was the *in situ* detection of a cleaved glycyl tyrosine at the active site of carboxypeptidase A.¹⁴

4.1 Trapped Hemiketal Intermediates: Shikimate Synthetase and Mimics for Protease Intermediates

In the case of shikimate synthetase (EPSP synthetase, Scheme 1), it has been possible to detect a tetrahedral intermediate formed by attack of shikimate-3-phosphate (S3P) on phosphoenolpyruvate (PEP) along the kinetic pathway by both low temperature solution NMR in a cryosolvent (10% glycerol at 6°C) and solid state NMR methods.^{15–17} A recent SSNMR study of EPSP synthetase also delineated the structure of the S3P–glycophosphate inhibitor of this enzyme.¹⁸ Both the solution and the solid state linewidths were quite broad, but the solution linewidth was significantly narrower than that of the solid state and the sensitivity appeared to be better. Here the chemical shift of the tetrahedral carbon in the hemiketal intermediate was found at ca. 100 ppm as expected, while the substrate alkene was found at ca. 160 ppm, so they could be distinguished easily simply using the isotropic shift. A comprehensive and practical perspective on the future of low temperature solid state NMR of proteins has recently been published.¹³

During the catalysis of an amide or ester hydrolysis reactions, a tetrahedral hemiketal intermediate is formed by attack of an enzyme serine or cysteine side chain or a bound water molecule on substrate carbonyl. This type of reaction has been extensively studied via inhibitors. Stable intermediate mimic compounds are made by the principle of proximity: the pseudoscicile carbonyl is localized near the attacking serine by some other covalent attachment, such as some of

Scheme 1

the covalent irreversible inhibitors of serine proteases used in preparative biochemistry, for example tosylphenylalanyl chloromethyl ketone (TPCK). Other inhibitors are based on the idea of replacing the reactive carbonyl with a more reactive aldehyde group: in the case of proteases, this means that the P_1' sites (and more distant sites on the C terminus of the substrate) are vacant. For these examples detection of the hemiketal mimic of the intermediate is straightforward using ^{13}C CP MAS or the carbonyl ^{13}C -labeled inhibitor, since the carbonyls resonate at 170–200 ppm and the hemiketal near 100 ppm (Scheme 2). Solid state carbon NMR of these trapped hemiketal complexes has facilitated confirmation of an intact protease active site in a variety of organic solvents in a detailed and quantitative fashion, despite the poorly defined amorphous nature of the sample.¹⁸

To produce a stable mimic of the hemiketal species, the carbonyl group has been replaced by a phosphate group, resulting in phosphoramidate and phosphinate transition state analog compounds for proteases. Phosphorus NMR of a phosphoramidate inhibitor of thermolysin (Scheme 3) shows a major perturbation of the ^{31}P CSA values upon binding to the enzyme, particularly in the case of benzoxycarbonyl Phe–phosphoramidate–Leu–Ala (ZFP^PLA) which has a 60 pM binding constant.¹⁹ Such massive changes are indicative of a change in geometry and bonding character, presumably because of tight coordination of the phosphate with the zinc cofactor. A thorough discussion of the trends in CSA for phosphates has been published²⁰ but such an analysis for phosphinates or phosphoramidates, particularly including the effects of metal chelation, is lacking.

In the study of thermolysin it was also established that there is no major perturbation to the nitrogen environment and that the P–N bond length was essentially unaffected by binding. These results imply that binding-induced perturbations on the phosphoramidate moiety mainly involve complexation of Zn by the oxygens, which was not clear from crystallography.

4.2 Amide Bond Formation and Cross-Linking

Another classic reaction type involving a tetrahedral transition state is provided by the amide bond-formation reactions. These often begin by phosphorylation of a carboxylic acid to form a good leaving group, followed by attack at the carbon by a neutral amine to form the tetrahedral complex. A phosphinate mimic of such an intermediate is a slow-binding inhibitor of the enzyme, D-Ala–D-Ala ligase (Scheme 4). Demonstration of the phosphorylation of this inhibitor at the active site by solid state NMR was accomplished using both homonuclear dipolar methods and chemical shift analysis;²¹ the values of the ^{31}P chemical shift anisotropy of the phosphinate changed dramatically upon binding indicating a covalent modification of the phosphinate to a phosphophosphinate (see Scheme 4). These results confirmed the analogy with proposed active-site chemistry of the substrate and explained the need for ATP. The poor stability of the phosphophosphinate species precluded detection by chemical methods, so an in situ probe was required.

Similar studies concerning inhibitors of glutamine synthetase are in progress (unpublished). The phosphorus NMR spectrum of the bound-state inhibitor was difficult to detect in the solution state, mainly because of the poor solubility of this membrane-associated enzyme. Moreover, in solution NMR spectra nonspecifically adhered phosphates gave rise to large and sharp signals. The signals due to these phosphates were weak and broad in the solid state spectrum. These differences in relative intensity are probably due to the relative mobility and strengths and specificity of binding constants, and they produce an accidental but very useful editing of the solid state spectrum.

Transglutaminases catalyze cross-linking of glutamine and lysine side chains for a variety of important structural proteins. Their mechanism involves a critical thioester–acyl enzyme intermediate (Scheme 5) and their inhibition has been of

Scheme 4

Scheme 5

general medical interest. Recently, solid state NMR was used to prove that halodihydroisoxazole inhibitors also form covalent imino thioether complexes at the active site.²² In this project the signal from the ^{13}C -labeled inhibitor was not detected by solution NMR methods when the inhibitor was bound to the 76.6 kDa enzyme, but the signal was readily detected by SSNMR. Tensorial information was not reported.

A combination of selective labeling, CP MAS, and sophisticated ^1H - ^{15}N - ^{13}C double cross polarization filtered solid state NMR approaches has allowed the in situ determination of chemical cross-links in a variety of structural, exoskeletal, and peptidoglycan structures. In the case of bacterial peptidoglycan structures the extent of cross-linking was determined.²³⁻²⁵ In the case of insect cuticle,^{26,27} unambiguous chemical shift and dipolar evidence was presented for an unusual cross-linked structure with direct catechol-histidyl bonds (Scheme 6). Such a structure is also likely to occur for the Black Coral skeleton.²⁸ Studies of the adhesive plaques from mussels indicate that the cross-linking in the protein glue does not involve lysine.²⁹ In these examples, in situ detection is of particular importance. Analogous methods have also been used to account quantitatively for small molecule bacterial metabolism.^{30,31}

Scheme 6

4.3 Other Mechanism Based Inhibitors: Schiff Base, etc

For several proteins, Schiff base or imine linkage at the enzyme active site has been confirmed based on chemical shifts, and the ionization state of the nitrogen has also been measured. In two cases the limited stability and insolubility of the enzymes made SSNMR an attractive approach. The usual tensor values for Schiff bases are quite distinct as compared with the amines from which they would usually be formed.

In the pyridoxylphosphate (PLP)-dependent reaction of alanine racemase (Scheme 7), transaldimination of the resting state PLP-lysine imine to form the alanine(substrate)-PLP imine has been proposed. Alanine phosphonate is a slow-dissociating inhibitor of alanine racemase. Solid state NMR data indicate that this compound forms a protonated imine with PLP at the active site, thus confirming that inhibition proceeds by the same mechanism as has been proposed for catalysis.³²

In bacteriorhodopsin the Schiff base linkage between the retinal and a lysine side chain has been demonstrated by ^{15}N tensor analysis,³³ and it is known now to be protonated in all states studied with the exception of the 'M' photointermediate (Scheme 9). The effects of the counterion on the chemical shift appear in the middle and deshielded only tensor elements (δ_{22} and δ_{11}) in a fairly systematic fashion, indicating that tensorial information will be useful for assigning the causes of changes in shift for this case.⁴

It is worth noting for comparison that the active-site chemistry and Schiff base formation of an enzyme of molecular weight 280 000 has been studied using ^{15}N and ^{13}C solution NMR with direct detection methods at elevated temperature (37°C), employing samples which were not only isotopically enriched but also had directly attached protons substituted with deuterium.³⁴ Some of the reported linewidths were less than 1 ppm. In this study it was established that porphobilinogen synthetase, which catalyzes the first common step of tetrapyrrole synthesis, proceeds via a Schiff base between C-4 of 5-aminolevulinic acid (ALA) and an active site lysine. Solution NMR of the 4-C labeled ALA indicated formation of a Schiff base with *E* stereochemistry following enzyme modification by methanethiosulfonate, but in the holoenzyme it appeared at a shift characteristic of a deprotonated amine. Determination of the protonation state of the Schiff base was ambiguous, presumably because of rapid proton-transfer reactions.

Scheme 7

* The species of interest was selectively detected, despite a crowded spectrum, by selective (DANTE) irradiation of C-15 whereby C-16 and C-15 were correlated.

Scheme 8

An unusual example of a mechanism-based active-site inhibitor is the 14,15-secoestra-1,3,5(10)-triene-15-yne-3,17 β -diol, a highly modified steroid inhibitor of estradiol dehydrogenase (Scheme 8). Oxidation of the hydroxy group at the 17-position to the corresponding ketone results in the formation of an yne-one. A subsequent Michael addition involving its yne-one fragment and nucleophiles in the enzyme active site (both lysine and cysteine) was demonstrated in situ by CP MAS.³⁵

5 CONFORMATIONAL ANALYSIS AND PROTEIN STRUCTURE

Another classic application of chemical shift analysis in solid proteins has been in situ detection of constrained conformations, such as changes in a dihedral angle accompanied by alteration of the partial double bond character or steric congestion. For such studies the anisotropic shift information is usually more definitive because a perturbation often appears specifically in one tensor element, and this observation will help in establishing its origin.

5.1 Retinal

Some of the earliest biological applications in conformational analysis of enzyme active sites by CSA resulted in the determination of the conformation of retinal in the resting states of bacteriorhodopsin (BR) and rhodopsin (Scheme 9). Many of these conclusions have subsequently been arduously confirmed by rotational resonance distance measurements and dynamics measurements. The so-called gamma *gauche* effect was used extensively to determine conformation in the polyene chain: in ^{13}C NMR this effect refers to the observation of a 5–10 ppm additional shielding due to steric crowding for the carbons in a polyene directly flanking a *cis* double bond.^{36,37} Oddly, the specific tensor element that exhibits this effect seems to depend on the particular example, but for typical

polyenes the effect is normally seen in the most shielded element (δ_{33} , which is normal to the polyene plane³⁷). Measuring the full CSA values could be useful in the diagnosis of the origin of a gamma *gauche* effect. Application of CSA analysis to retinals led to the conclusion that bR is 6-*s-trans* in all states in the photocycle, while rhodopsin is 6-*s-cis*. Compounds which are 6-*s-cis* show shielded values for the 5-carbon relative to the corresponding 6-*s-trans* isomers (here the change appears in the *least* shielded element). A similar effect is expected for the *Z* (*syn*) versus *E* (*anti*) nitriles and Schiff bases (here it apparently affects the *middle* tensor element of the flanking carbons). This effect was also used to predict that the dark adapted bR555 is 13-*cis* C–N *syn*, light-adapted bR568 is 13-*trans* C–N *anti*, and the M and N photointermediates are 13-*cis* C–N *anti*. These studies and parallel studies of rhodopsin have been reviewed recently³⁸ (see also *Bacteriorhodopsin and Rhodopsin*). Similarly, observation of the isotropic shift of the 14- ^{13}C -labeled spheroidene carotinoid in the photosynthetic reaction center (RC) from purple nonsulfur bacteria has been used to conclude that the conformation is 15,15'-*Z* in the protein.³⁹

5.2 Amide Conformation by CSA Values

Several surveys of the correlation between carbon or nitrogen shift and protein backbone conformation have been reported, encompassing solution^{40–42} and solid state NMR data^{43–47} (see also *Solid Biopolymers*). The most clear correlations utilize the carbon shift of the α -carbon or the carbonyl carbon, which are both ~ 5 ppm more deshielded for the α -helix (56 and 175 ppm typical values, respectively) than for the β -sheet (52 and 170 ppm typical values, respectively). The reverse trend appears to be true for the β -carbon (26 ppm for the α -helix and 30 ppm for the β -sheet) and the proton of the NH (ca. 8.1 ppm for the helix and 8.5 for the sheet). The α and β shifts are also dependent upon the type of amino acid side chain. Some correlations between side chain conformation and carbon chemical shift have also been observed for the aromatic side chains.⁴⁸

The situation for ^{15}N shifts for the amide backbone is more complicated. Hydrogen bonding, backbone and side chain conformation, and local electrostatic field all contribute to give a range of approximately 30 ppm. Although the dispersion is quite good, no clear-cut trends with any one structural parameter are observed.⁴⁰ The chemical shifts in solution and solid state for staphylococcal nuclease have been compared; assignments made with solution NMR methods often apply to solid state samples as well.⁴⁹ This lends further support to the notion that the shifts are relating specific information about the folded form of the protein and this observation will be useful in planning further studies of proteins.

5.3 Amide Conformation by Static Oriented Samples

A novel application of chemical shift anisotropy to obtain structures of proteins involves the measurement of partially ordered and static samples as a function of sample orientation in the applied field.^{50–52} This approach has allowed the structural characterization of coat proteins from filamentous bacteriophage, a particle of 16 MDa molecular weight.

	¹³ C retinal	δ _{iso}	δ ₁₁	δ ₂₂	δ ₃₃ (ppm)

Application of similar methods to gramicidin has resulted in a molecularly detailed three-dimensional structure of the protein in the hydrated lipid bilayer.⁵³

5.4 Mobility Probed by CSA Studies

The partial averaging of chemical shift anisotropy in static samples, in conjunction with relaxation measurements, has

been used to determine the internal mobilities and dynamics of several structural proteins in the solid state on the ms to ns timescale.^{54–56} CSA values are often used for analyses of ns timescale internal motions via T_1 values in solution NMR. Frequently the ‘uniaxial’ approximation is made, i.e. $\eta = 0$ or $\delta_{xx} = \delta_{yy}$. Figure 1 illustrates that this is a good approximation for the ¹³C tensor of some alcohols, where the unique axis is most shielded and is along the C–O bond, or for some methyl groups where it is along the C–C bond, or for some aromatic carbons where it is orthogonal to the plane. However, this approximation is poor for many cases such as the backbone carbons of a protein and nitrogens in cyclic compounds. Orientations are described elsewhere in the text for the amides and carboxy groups.

6 IONIZATION AND HYDROGEN BONDING

Identifying the ionization states of the amino acid side chains is fundamental to an understanding of the energetics of protein folding. Electrostatic interactions in proteins are also dominant interactions for analyzing enzyme mechanisms. NMR is a proven method for determining ionization state and hydrogen bonding environment, and we will discuss particular aspects of solid state measurements in the following.

It is useful first to summarize the functional groups of interest and their typical behavior. The ‘permanently’ ionized arginine side chains are rarely found in protein interiors and normally are engaged in ion pairing on the surface of the enzyme or in the active site; the ‘sometimes’ ionized histidyl, aspartic, glutamic, and lysine side chains can be found in the protein interior, and often participate in important interactions at the active site. The ionization states of these four side chains can sometimes be inferred from the structural context, for example by X-ray crystallography, but this approach is prone to error in lower resolution structures. Although spectroscopic characterization could give an unambiguous determination of both the ionization state and the hydrogen-bonding strengths for carboxyl as well as imidazole side chains, it has been undertaken in few cases.

The NMR spectra of the residues that have commonly been observed to change ionization state (His, Asp, Glu) have been studied systematically in the solid state and it is clear that more information is available from the complete tensor analysis than from the isotropic values alone. SSNMR might also be useful for the study of residues which are normally capable of forming moderate strength hydrogen bonds but rarely change ionization state stably (alcohols, amides, amine, arginine); fewer model compound studies have been done for these cases.

6.1 Nitrogen-15 Studies of Histidine

There have been several studies of the ¹⁵N tensors of histidine. The values are very much affected by the ionization state of the imidazole ring. The nitrogen with attached proton exhibit isotropic shifts of 160–200 ppm and a breadth ($\delta_{33} - \delta_{11}$) of ca. 200 ppm. The more deshielded values correspond to stronger hydrogen bonding. The nitrogen with attached proton shows an isotropic shift of 235–250 ppm and a breadth of ca. 380 ppm and here stronger hydrogen bonding

Scheme 10

leads to shielded values.^{57–59} In the solution state, near neutral pH values, the proton transfer reactions of histidine are very fast, the ionizable ^1H resonances are undetectable, and the ^{15}N spectrum can be a weighted average of various tautomers and ionization states. The solid state spectrum with full tensor information could, in principle, indicate more clearly the predominant species present, whenever a chemically meaningful solid state preparation can be prepared. It is noteworthy, however, that in certain cases the solution ^{15}N NMR of histidine did give an unambiguous indication of the average ionization state in an enzyme (including specification of the tautomer and hydrogen-bond strength) and this approach has been used in several enzyme mechanistic studies.^{59,60}

Nitrogen-15 CP MAS analysis has been applied to the active-site histidine in α -lytic protease (Scheme 10). These studies brought into focus the results of diffraction and solution NMR studies and cleared up a long-standing confusion concerning the interpretation of the hydrogen-bonding network at the active site of the serine proteases.⁶¹ The crystallographic conditions apparently substantially affected the pK_a value of the active-site histidine and as a result the organization of the hydrogen-bond network was artifactual. In particular, in the absence of crystallization, the enzyme would be active at pH 7, the active-site His would be neutral, and would engage in hydrogen-bond formation with serine and aspartic acid. However, in some studies the addition of salts for precipitation raised the pK_a value of the histidine so that it was ionized at pH 7 and consequently the hydrogen bond with serine was artifactually broken. It is known from other studies (unpublished) that some common crystallization salts inhibit a variety of enzymes, despite the fact that under the same conditions the general fold of the protein is intact. Measurements of ^{15}N shifts of active-site histidine have also been used to probe the patency of serine protease active sites in organic solvents;⁶² in certain solvents the enzyme was inactive but native-like active sites were indicated by NMR. Unfortunately, anisotropies were not reported for the protein studies.

6.2 Nitrogen-15 Studies of Amine, Amide, and Guanidine

The ^{15}N chemical shift anisotropy of protonated amines is quite narrow.⁵⁷ The protonated guanidino group ^{15}N NMR has been studied both in model compounds and in the arginines of bacteriorhodopsin. The chemical shift anisotropy for the ϵ and δ -nitrogen of the guanidino group is also quite narrow, so that anisotropy was effectively undetected at low spinning speeds. Interestingly, counterion effects are observed on the δ -nitrogen but not on the ϵ -, both for the model systems and the proteins. The chemical trends in the δ -shift are currently under analysis.⁶³

Amide ^{15}N shift anisotropy has been extensively studied. Tensors are generally quite broad with isotropic values at ca. 118 ppm and widths of 200 ppm. The tensor elements have been shown to shift further to high frequency with increasing hydrogen-bonding strength (particularly the δ_{33} tensor element).^{64,65} Careful determinations of both the values of the tensor elements and their spatial directions have been reported for several amides, and variation in the values but not the directions were observed⁶⁶ with the most shielded element being near the C–N bond (offset by 9°) and the middle element out of the amide plane. It is noteworthy that, in general, the tensors are not strictly uniaxial, which may be important for the study of dynamics in proteins via the measurement of nitrogen relaxation.

6.3 Carbon-13 Studies of Carboxy Groups

Carbon-13 CSA is a good probe of the environment of the carboxy group and is readily interpreted. The protonated state of the carboxyl group in aspartic and glutamic acids in solid state amino acids and proteins can easily be determined from the δ_{11} values of the carbon chemical shift tensors which are below 250 ppm for deprotonated and above 250 ppm for protonated groups as indicated schematically in Figure 1.⁶⁷ The δ_{22} element for both protonated and deprotonated forms varies strongly as a result of hydrogen bonding and correlates with established measures of hydrogen bonding, namely the IR stretching frequencies of the carbonyl and the asymmetric stretching frequency for the protonated and deprotonated carboxy groups, respectively, and $\text{O}\cdots\text{H}$ hydrogen-bonding distances from the carbonyl of protonated acids to the nearest proton donor.

There is a fixed geometry for the protonated acids and a variable and complicated geometry for hydrogen-bond interactions in deprotonated carboxylates. Correspondingly, the correlations between NMR, IR, and diffraction data seem more convincing for the protonated acids. In contrast to the CSA, the average or isotropic chemical shift for the carbon in carboxy groups is rather insensitive to ionization state and hydrogen bonding. Therefore, measurements of the tensor values in the solid state for the carboxy group can be much more informative than solution measurements. These trends have subsequently been explained by ab initio methods.

SSNMR ^{13}C measurements have been used to delineate the protonation state of the transition-state analog inhibitor of triose phosphate isomerase (TIM), phosphoglycolic acid (PGA)⁶⁸ (Scheme 11). The carboxy group is deprotonated when bound to TIM and is involved in a strong hydrogen bond, which established that it is a mimic of the catalytic

Scheme 11

intermediate in which charge develops on the carbonyl of the substrate dihydroxyacetone phosphate, and is stabilized by nearby histidine and lysine residues.

The aspartic acid residues in bacteriorhodopsin have been labeled and the CSA measured for the carboxy side chains. These spectra gave an unambiguous ionization state for several of the active-site residues.^{69,70} Some of the carboxy groups also show evidence of motional averaging of the CSA, so for determination of the ionization and hydrogen-bonding strengths, corrections for the motional averaging must be made. Asp-85, -96, and -212 are necessary amino acids for proton pumping activity. Asp-85 and -212 are known to be on the cytosolic side of the membrane (the proton 'sink'). Based on these CSA values, both are clearly deprotonated, and Asp-85 is engaged in a relatively strong hydrogen bond. Asp-85 is perturbed by the light-induced conversion from bR555 to bR568, although it appears to remain deprotonated. These observations would support a model in which it is in a hydrogen-bonding or counterion interaction with the Schiff base. Asp-96, which is on the extracellular side (the 'source' for protons) is evidently protonated in dark and light-adapted bR based upon these CSA studies, and the values imply a rather weak hydrogen-bonding environment, perhaps a hydrophobic pocket. The intermediates of the photocycle, M and N, have been proposed to have Asp-85 protonated⁷⁰ and Asp-96 deprotonated, respectively, but further investigations of these points by low-temperature SSNMR are necessary.

6.4 Carbon-13 Studies of Tyrosine and Amides

The ^{13}C chemical shift anisotropies of the hydroxylated ring carbon of tyrosine and phenol-containing organic solids have been studied (e.g. 4- ^{13}C -tyrosine). The corresponding anions are readily identified on the basis of deshielded δ_{22} values: the neutral, protonated forms are in the range 151–170 while the anions are 180–205. Both δ_{11} and δ_{33} appeared to be less sensitive to environment, with values of 57–73 and 233–258, respectively.⁷¹ There was some indication that δ_{22} is also sensitive to hydrogen bonding but this effect was not systematically studied. Applications to the study of bacteriorhodopsin showed that although the tyrosinate is detectable under very basic conditions (when the protein is presumably unfolded), under normal conditions, even for catalytic intermediates, there is no evidence for tyrosinate formation.^{71,72} In these studies there was difficulty in resolving several tyrosines in one protein. Similarly, the 4- ^{13}C -tyrosine in the reaction centers of purple nonsulfur bacteria were detected, but the signals had to be deconvoluted by lineshape analysis due to poor resolution.⁷³ For the interpretations of

the chemical shift spreads in both proteins, additional database work would probably be helpful.

Systematic trends in the ^{13}C CSA of amides as a function of the amino acid, the hydrogen-bonding environment, and the backbone geometry have been reviewed elsewhere.^{74,75} The effect of hydrogen bonding on the carbon shift is to cause a deshielding effect on the middle tensor element, quite similar to the effect observed for protonated carboxylic acids.

7 CONCLUSIONS

Solid state NMR heteroatom chemical shift measurements of selectively-labeled proteins have had an important role in several problems in protein structure and active-site chemistry. For these kinds of studies, solid state NMR has advantages over solution state NMR when the protein is not very soluble under the conditions of interest, or when direct comparison with crystallography is desired; however, when the enzyme is very large (above 100 kDa) and rather soluble, the comparison of sensitivity between solid state and solution state NMR methods is unclear. In several important cases the analysis of the tensor in the solid state provides more information than the isotropic value alone: this analysis could allow the assignment of the physical origin of an environmentally-induced shift.

There have been many strong applications of chemical shift analysis for conformation or structure studies of solid proteins in the past two decades. For example, shift measurements including analysis of anisotropy were the first definitive tool for determining the conformation of retinal in the retinal-binding proteins bacteriorhodopsin and rhodopsin. The shifts of oriented, static samples have been used in structure determination for phage-coat proteins and intrinsic membrane proteins such as gramicidin. The partial averaging of the anisotropy has been used to probe mobility in a variety of proteins, mainly structural proteins such as collagen. Changes in isotropic shifts have been used to determine the extent and type of cross-linking in peptidoglycan, cuticle, and exoskeletal proteins.

Solid state shift measurements have been used extensively to probe active-site chemistry in enzymes as enumerated in detail in this review. The covalent modifications are usually apparent from the values of the isotropic shifts alone and several examples are illustrated in the Schemes. The studies of nonbonded interactions at the enzyme active site by heteroatom shift tensors are discussed, especially hydrogen bonding and ionization state changes of imidazole and carboxy groups viewed by ^{15}N and ^{13}C shifts, respectively. For these two functional groups a CSA database for chemical interpretation has been partly assembled and demonstrates the utility of full tensor analysis, while for other functional groups the database is still small.

1 INTRODUCTION

Carbonic anhydrase is a zinc-containing enzyme catalyzing the reversible hydration of carbon dioxide as well as the hydrolysis of certain esters and the hydration of aldehydes.¹ Mammals have seven carbonic anhydrase genes encoding different isozyme forms. The cytosolic isozymes, I, II, and III ($M_r \approx 29\,000$) have been studied in particular detail. They are stable, highly soluble, monomeric proteins which are readily purified in large quantities. These properties have contributed to make carbonic anhydrase an excellent 'beginner's enzyme' for spectroscopists wishing to apply their methods to biochemical systems. The catalytic and inhibitor-binding properties of Co(II)-substituted carbonic anhydrase are very similar to those of the native Zn(II)-enzyme. Therefore, the Co(II)-enzyme has been frequently used as a functional model in spectroscopic studies.

To our knowledge, the first NMR study of carbonic anhydrase was published in 1969 and involved measurements of ^{35}Cl linewidths to illustrate the interaction between inhibiting chloride ions and the zinc center.² Since then well over 100 papers have appeared describing a variety of NMR investigations of this enzyme system. The major findings are summarized here in a biochemist's rather than an NMR spectroscopist's perspective. We apologize to all those whose papers are not cited because of the limited space allotted to us.

2 NMR STUDIES OF THE ACTIVE CENTER

The active center of carbonic anhydrase is located in a 15 Å deep cavity which is about 15 Å wide at the entrance. The zinc ion is near the bottom of the cavity and firmly bound to three imidazole groups from His-94, His-96, and His-119 in a tetrahedral geometry with H_2O or OH^- as the fourth ligand. Isozyme I from most species has three additional active-site histidines, His-64, His-67, and His-200, whereas isozyme II has only one, His-64.¹

To test if one of these histidines corresponds to the catalytic group with pK_a ca. 7, postulated from kinetic results to

control CO_2 hydration as well as ester hydrolysis,¹ Campbell et al.³ recorded ^1H NMR spectra of human isozymes I and II (previously called B and C, respectively) at various pH values in $^2\text{H}_2\text{O}$ solutions. They could identify resonances from the C ϵ 1 protons of all solvent-exposed histidine residues including the three metal ligands. Resonances from active-site residues were discriminated from those from surface residues by their sensitivity to inhibitors, and individual assignments of most active-site resonances could be made. The results showed that the only active-site resonances reflecting the behavior of the catalytic group were those from some of the ligands. It was concluded that the catalytic group is not a titratable histidine but must be tightly associated with the metal center. The current model involves the zinc-bound H_2O ionizing to OH^- , but an alternative hypothesis with a ligand imidazole ionizing to an imidazolate anion had also been proposed on the basis of similar NMR results.⁴

This hypothesis was tested by Campbell et al.³ who observed exchangeable NH proton resonances located between 12 and 15 ppm. In human isozyme II, five of these were sensitive to inhibitors and to pH changes near pH 7 where the activity-linked group titrates. They could be observed over the whole pH range between 5.5 and 9.6. Three of these resonances were assigned to the ligand imidazoles. It was concluded that the imidazolate model is unlikely, since it requires a rapidly exchanging NH proton which would be unobservable under the conditions of these measurements.

Bertini et al.⁵ detected a number of paramagnetically shifted resonances in the ^1H NMR spectra of Co(II) substituted carbonic anhydrase. They could assign pH-sensitive resonances in the 50–65 ppm range to the NH protons of the ligand imidazoles. Their results confirmed that the imidazolate model for the catalytic group can be ruled out.

The degree of resolution of paramagnetically shifted resonances from the Co(II)-enzyme seems to depend on the coordination geometry of the metal ion. When the high spin Co(II) ion is tetrahedral, as in uninhibited isozyme II or in the NCO^- adduct, electronic correlation times are relatively long ($\tau_e > 10^{-11}$ s) and many resonances are broadened beyond detection. In the presence of certain anionic inhibitors, such as SCN^- , ClO_4^- , and NO_3^- , the Co(II) ion is presumably pentacoordinated with characteristically short τ_e values in the range $(3-6) \times 10^{-12}$ s.⁶ In these cases, a multitude of shifted resonances has been observed. In an extensive study of the ClO_4^- and NO_3^- adducts of bovine Co(II)-isozyme II using 1D NOE as well as 2D ^1H NMR, Banci et al.⁷ assigned several resonances to specific active-site protons. Such data might be particularly useful in future structural studies of site-specific mutants.

The close link between the metal ion and catalytic properties has been further illustrated in NMR studies of ^{113}Cd -substituted enzyme.^{8,9} For example, Jonsson et al.⁸ found that the chemical shift of the ^{113}Cd resonance from human isozyme II varied continuously from 229 ppm at low pH to 275 ppm at high pH, indicating a rapid exchange between a low pH form and a high pH form (presumably a metal-bound H_2O ionizing to OH^-). The estimated pK_a of 9.2 agrees reasonably well with that determined from the pH-dependence of the esterase activity. The binding of HCO_3^- resulted in a shift to 216 ppm. In the presence of the powerful inhibitor $^{13}\text{CN}^-$, a doublet centered at 354 ppm with a ^{113}Cd - ^{13}C spin

coupling constant of 1040 Hz provided evidence of a direct metal–cyanide interaction.

Human carbonic anhydrase I is partially inactivated by bromo- or iodoacetate.¹ The reaction specifically occurs at Nε2 of His-200 resulting in an *N*-carboxymethyl derivative. Khalifah et al.¹⁰ recorded the ¹³C NMR spectrum of [1-¹³C]carboxymethyl human isozyme I as a function of pH detecting two ionizations with *pK_a* values of 6.0 and 9.0. These and subsequent data¹¹ indicated that the carboxy group of the carboxymethyl moiety coordinates to the metal ion in the intermediate pH range, while it dissociates from the metal ion as the imidazole ring becomes protonated around pH 6. The *pK_a* of 9 probably reflects the displacement of the carboxy group by OH[−].

3 WATER PROTON RELAXATION IN METAL-SUBSTITUTED CARBONIC ANHYDRASES

An early NMR study by Fabry et al.¹² seemed to upset the notion that the catalytic group of carbonic anhydrase is an H₂O molecule, coordinated as a fourth ligand of the tetrahedral metal ion, and ionizing to OH[−] with *pK_a* near 7.¹ These authors measured the relaxation rates (*T*₁^{−1}) of water protons as functions of pH and Larmor frequency in the presence of Co(II)-substituted carbonic anhydrase. The paramagnetic contribution to the relaxation rate increased with pH along a titration curve with a *pK_a* value similar to that estimated from activity measurements. The data were compatible with the presence of one rapidly exchanging, metal-bound H₂O molecule at high pH, while it was suggested that there is no coordinated H₂O or, possibly, a slowly exchanging H₂O at low pH. Seemingly, the dilemma caused by these results has later been resolved. Thus, Koenig et al.¹³ have proposed a mechanism for the rapid exchange of a proton from Co(II)-bound OH[−] involving an unstable, pentacoordinated exchange intermediate with an additional water molecule in the coordination sphere. The low relaxation rate at low pH can be explained by the presence of inhibiting anions (such as sulfate) displacing metal-bound water and/or by the presence of a significant fraction of a low pH form with a shorter electronic correlation time such as in a pentacoordinated complex with two metal-bound water molecules.^{6,13}

Water proton relaxation has also been measured with other metal-substituted carbonic anhydrases to explore the properties of the metal-ion binding site.¹ In one of the most thorough studies, Kushnir and Navon¹⁴ measured *T*₁ and *T*₂ for both ¹H and ²H in the presence of the Mn(II)-enzyme in a mixed ¹H₂O/²H₂O solvent. They derived a hydration number of 1 and estimated an exchange lifetime for the Mn(II)-bound water of 75 ns.¹⁴

4 NMR STUDIES OF INHIBITOR BINDING

Inhibitors of the catalytic activities of carbonic anhydrase bind to the metal ion or in its close vicinity.^{1,15} There are three major classes of inhibitors, inorganic and organic anions, sulfonamides, and a variety of neutral, organic compounds. Representatives of all three classes have been studied by NMR.

Carbonic anhydrase very effectively relaxes the quadrupolar ³⁵Cl nucleus in Cl[−] ions.² This suggests a direct Zn²⁺–Cl[−] interaction in the enzyme. From the temperature-dependence of the ³⁵Cl[−] line broadening, Ward and Cull¹⁶ concluded that the chloride ions are in slow exchange and estimated a residence time of about 1 μs for the interaction with human isozyme I.

Cyanide is one of the most potent anionic inhibitors of carbonic anhydrase.¹ The observed ¹¹³Cd–¹³C spin coupling of 1040 Hz in the cyanide complex of ¹¹³Cd-substituted enzyme is clear evidence of a direct metal–inhibitor bond.⁸ The chemical shift position at ca. 76 ppm of ¹³CN[−] bound to native Zn(II)-enzyme has been taken to imply metal coordination.¹⁷ In view of these and other spectroscopic results,¹ it was quite unexpected that the crystal structure of the cyanide complex with native human isozyme II showed that CN[−] does not displace the zinc-bound H₂O molecule but is located in the vicinity of the metal ion at a distance of 3.4 Å.¹⁵ The significance of this result has been challenged by Bertini et al.¹⁸ who compared ¹³C linewidths from ¹³C¹⁵N[−] in the presence of bovine isozyme II containing ⁶⁷Zn (*I* = $\frac{5}{2}$) and ⁶⁴Zn (*I* = 0), respectively. They obtained considerably broader lines with ⁶⁷Zn than with ⁶⁴Zn and interpreted these results in terms of a direct zinc–cyanide coordination. However, the largest effects were observed at high temperatures (50–60°C) where the enzyme is not fully stable. In our opinion, the possibility that the observed effects are related to interactions of ¹³C¹⁵N[−] with a denatured state of the enzyme should not be ignored.

In crystals of human isozyme II, NCO[−] binds like CN[−].¹⁵ In the Co(II)-enzyme, however, large paramagnetic effects on *T*₁ for bound N¹³CO[−] suggest cobalt–cyanate coordination.¹⁸ Possibly, different binding modes are energetically favored by the Co(II)- and Zn(II)-enzymes, or there are two energetically similar binding modes for some anionic inhibitors such as NCO[−], and one of them predominates under the experimental conditions used in the crystal structure studies and another under the conditions used in spectroscopic studies.

The interaction between carbonic anhydrase and acetate ion has been the subject of several NMR studies. Lanir and Navon¹⁹ found evidence for two acetate-binding sites in ¹H NMR studies of the bovine Zn(II)- and Mn(II)-enzymes. Only one of these sites is linked to the inhibition of the catalytic activity, but both appeared to be rather close to the metal ion. The crystal structure of the acetate complex of human isozyme II reveals only the inhibitory site, and the location of the other site remains unknown. In the crystal structure, the carboxy group of acetate has a similar location as the NCO[−] ion (see above) and does not displace the metal-bound water molecule.¹⁵ However, one of the carboxy oxygen atoms is a weak Zn(II) ligand (Zn–O distance, 2.4 Å) in a distorted, trigonal bipyramid with His-96 and acetate in the axial positions. Bertini et al.²⁰ have arrived at similar structures for the acetate and formate complexes of bovine Co(II)-isozyme II. From the ¹³C relaxation rates of carboxyl-labeled inhibitors, they concluded that the anions are coordinated to the Co(II) ion. The relaxation rates of paramagnetically shifted ligand protons in the 200 MHz ¹H NMR spectra of these adducts suggested a pentacoordinated metal ion. Finally, ¹H NOE measurements connected the formate and acetate protons with resonances that could

tentatively be assigned to the active-site residues, Val-143 and Val-207, in 2D ^1H NMR experiments.

While Bertini et al.²⁰ sought structural information, Taylor et al.²¹ could calculate residence times in the μs range for the formate, mono-, di-, and trifluoroacetate adducts of human Co(II)-isozyme II from ^1H and ^{19}F linewidth measurements under conditions where slow exchange prevailed.

Aromatic sulfonamides are potent inhibitors of carbonic anhydrase. They bind to the metal ion as anions, RSO_2NH^- , displacing the coordinated water molecule.^{1,15} NMR evidence for this comes from the observation that the proton-coupled ^{15}N resonance of benzenesulfonamide bound to human isozyme I is a doublet.²² While X-ray crystallography cannot differentiate between O and N atoms, NMR has provided proof of nitrogen coordination. Thus, Evelhoch et al.²³ found a ^{113}Cd - ^{15}N coupling constant of 190–210 Hz in the ^{113}Cd NMR spectra of complexes between sulfon[^{15}N]amides and human ^{113}Cd -isozymes I and II. In a similar study using ^{111}Cd , Blackburn et al.²⁴ found a ^{111}Cd - ^{15}N coupling constant of 176 Hz for 4-fluorobenzenesulfon[^{15}N]amide bound to bovine ^{111}Cd -isozyme II. For 4-fluoro-*N*-hydroxybenzenesulfon[^{15}N]amide, A coupling constant of 249 Hz was observed.

Sulfonamides dissociate very slowly from the active site of carbonic anhydrase. Gerig and Moses²⁵ calculated a dissociation rate constant of 0.02 s^{-1} for the complex between pentafluorobenzenesulfonamide and human isozyme II from results of ^{19}F saturation transfer experiments. Their results also suggested that ring rotation is appreciably faster with a rate constant of 4 s^{-1} .²⁵

Imidazole inhibits human isozyme I by binding near the metal ion without displacing the coordinated water molecule.¹ This binding mode is compatible with the observation that the resonance assigned to the C ϵ 1 proton of the ligand His-94 undergoes a substantial ring current shift to lower frequency upon imidazole binding.³ The paramagnetic effects of Co(II)-carbonic anhydrase on proton relaxation rates in imidazole, 1,2,3-triazole, 1,2,4-triazole, and tetrazole have been taken to imply coordination to the metal ion.²⁶ In the case of 1,2,4-triazole this has been confirmed by crystallographic results on the complex with human isozyme II.¹⁵

5 NMR STUDIES OF SUBSTRATE BINDING AND INTERCONVERSION

Carbonic anhydrase is a very efficient catalyst of the reversible hydration of CO_2 . The most active form, isozyme II, can turn over 10^6 substrate molecules per second at 25°C .^{1,27} Simonsson et al.²⁸ estimated $^{13}\text{CO}_2$ - $\text{H}^{13}\text{CO}_3^-$ exchange rates from line broadenings in the slow exchange region and found that the maximal rate of catalyzed exchange is the same in $^1\text{H}_2\text{O}$ and $^2\text{H}_2\text{O}$, and is independent of added buffers in contrast to the maximal rate of turnover measured by conventional steady state kinetic techniques. This combination of kinetic data obtained at chemical equilibrium and in the steady state, respectively, has been of critical importance for the understanding of the catalytic mechanism of the enzyme.²⁷

Considerable efforts have been made to determine how the substrates, CO_2 and HCO_3^- , interact with the active center. NMR has been an important tool in this work in

which the paramagnetic effects of the Co(II)-, Cu(II)-, or Mn(II)-enzymes on the relaxation rates of $^{13}\text{CO}_2$ and $\text{H}^{13}\text{CO}_3^-$ have been measured. In summary, these measurements have shown that HCO_3^- is most probably coordinated to the metal ion while the binding of CO_2 is very weak.

Thus, Williams and Henkens²⁹ measured T_1 values and linewidths for the $^{13}\text{CO}_2$ and $\text{H}^{13}\text{CO}_3^-$ resonances in the presence of the catalytically active human Co(II)-isozyme I. From the T_1 values for HCO_3^- (rapid exchange), a Co(II)- ^{13}C distance of $3.2\text{ \AA}$ was calculated, while the paramagnetic contribution to T_2 (slow exchange) gave a HCO_3^- residence time of $44\text{ }\mu\text{s}$ for this low-activity form of carbonic anhydrase.

Bertini et al.³⁰ used the catalytically inactive Cu(II)-enzyme to study the interaction with $^{13}\text{CO}_2$ and $\text{H}^{13}\text{CO}_3^-$ at high CO_2 pressures. From the results of T_1 measurements, the authors concluded that CO_2 binds very weakly to a site near the metal ion. The HCO_3^- ion exchanges slowly with the Cu(II)-enzyme and residence times of 2.3 ms and 0.2 ms were estimated for human isozyme I and bovine isozyme II, respectively.

Substrate interactions with human Mn(II)-isozyme I have been studied by ^{13}C NMR. This enzyme has some catalytic activity and Led and Neesgaard³¹ used magnetization transfer techniques to estimate a maximal exchange rate constant of 400 s^{-1} which is about 100-times smaller than the value for native isozyme I.²⁸ A variety of additional parameters were calculated from results of extensive relaxation rate measurements, including an Mn(II)- ^{13}C distance of $2.7\text{ \AA}$ for the HCO_3^- complex.

Rather few studies have been published on the aldehyde hydration activity of carbonic anhydrase. However, Chesnovsky and Navon³² used ^1H saturation transfer to measure chemical exchange between the hydrated and unhydrated forms of acetaldehyde catalyzed by bovine isozyme II. A careful analysis of the observed linewidths indicated that acetaldehyde also binds to sites distinct from the active site.

6 FUTURE PROSPECTS

In the past, NMR has given valuable contributions to our understanding of the catalytic mechanism of carbonic anhydrase and its interactions with various ligands. About 80% of the NMR papers on this enzyme were published between 1971 and 1985, and other techniques have dominated the recent carbonic anhydrase literature. However, since the human isozymes I, II, and III have been expressed in a bacterial system, which permits general or selective labeling with suitable isotopes, we expect that this 'beginner's enzyme' and site-specific mutants thereof will be used in future multidimensional NMR studies despite its relatively large molecular mass of about 29 kDa.^{33,34}

Carbonic anhydrase has become a popular model for studies of protein folding, and has been shown to fold into its native structure via a molten globule intermediate. Assignment of peptide NH hydrogens in 3D NMR spectra of ^{15}N -labeled enzyme will form the basis for deuterium-exchange experiments which can give detailed structural information on the molten globule and other intermediate states.

1 INTRODUCTION

In this review cell suspensions can be unicellular organisms or isolated cultured cell lines of mammalian or plant tissues. In connection with cellular NMR studies, both terms ‘in vivo’ and ‘in vitro’ are in use. This semantic differentiation may be misleading, because most isolated mammalian cells represent an in vitro system, whereas blood cells, many plant cells, and microorganisms represent true in vivo systems. For simplification, the term in vivo will be used if viable intact cells are considered. True in vitro systems are perfused subcellular compartments like isolated mitochondria and chloroplasts or cellular extracts.

In vivo NMR spectra from intact human organs or animal models are obtained within several minutes to half an hour. Because of the intrinsically large volume needed for a good signal-to-noise ratio, the signals obtained do not originate from a homogeneous cell population. The selected tissue normally consists of metabolically different cell types. In order to assign metabolites to individual cell types, isolated cell cultures are preferred although they are missing the specific intercellular communication as in the case of neurons and glia cells. This constraint limits the significance of uniform cellular models with respect to the actual situation in vivo. On the other hand, uniform cell populations allow control over biochemical and physiological parameters that are not independently accessible in intact organisms or perfused organs. Studies of cells give access to elementary metabolism such as biochemical pathways, variations of biochemical pathways in different cell types, principles of cellular homeostasis, intra-/extracellular transport phenomena, etc. The NMR technique is able to monitor the metabolism of complex biological systems noninvasively. No prior separation of individual compounds is necessary. Even dedicated multipulse techniques are applicable to the in situ identification of metabolites. These aspects alleviate the intrinsic disadvantage of NMR, namely its low sensitivity.

This review will deal primarily with biochemical topics of cellular NMR spectroscopy to exemplify the potential of this method rather than to evaluate the advantages of individual NMR sensitive nuclei, which are primarily ^1H , ^{13}C , ^{15}N , ^{19}F , ^{23}Na , and ^{31}P in this context. Several reviews have described various aspects of cellular NMR spectroscopy in great detail.^{1–6}

2 METHODOLOGY

The inherently low sensitivity of NMR spectroscopy demands 10^7 – 10^{10} cells per mL (corresponding to 1–100 mg mL^{-1} w/w) within the receiver coil. Cells with a very small volume like prokaryotic cells may require an order of magnitude more cells depending upon the field strength used. In general, prokaryotic cells and unicellular eukaryotic plant cells,⁶ but also blood cells^{7,8} and, in particular, a large variety of human and other mammalian tumor cell lines,^{9–12} proliferate fast enough or are available in sufficiently large quantities to meet this requirement.

In order to get the full benefit of in vivo studies the cell samples have to be kept under viable conditions, and the interpretation of the spectra has to be based on reliable assignment techniques and on the quantitation of metabolite concentrations.

2.1 Cellular Extracts

A simple but time-consuming way to follow cellular metabolism is to extract parallel grown cell batches at different times. The cells will always be kept under optimum growth conditions and control of nutrient supply in the incubator. This procedure corresponds to the well-known invasive biochemical techniques like radiotracer methods. Studying extracts gains the benefits from the high-resolution conditions such as narrow linewidths, resolved coupling constants, better signal-to-noise ratio, and unlimited spectral acquisition time (i.e. metabolic concentration of a few μmol are detectable compared with ≥ 0.5 mmol concentration in vivo), applicability of multipulse and/or multidimensional techniques,¹³ and the avoidance of unfavorable nuclear Overhauser effects (NOE) in heteronuclear experiments¹⁴ (see Figure 1). Pulse label experiments with ^{15}N labeled precursor molecules may suffer from a nulling NOE in vivo if plant cells with high amounts of paramagnetic ions are recorded.

Proton NMR spectra from living cells are difficult to accumulate, because they are kept in an aqueous medium and need water suppression procedures (see Section 2.2). This is circumvented when studying cell extracts, as they are lyophilized and taken up in D_2O before recording.

Standard extraction techniques use perchloric acid (PCA) to obtain the water-soluble, low molecular weight metabolites.¹⁵ Cells are quickly rinsed before harvest with isotonic buffer to remove unwanted compounds from the nutrient medium or exported metabolites by the cells. Thereafter, the cells are immediately frozen with liquid nitrogen, extracted with cold PCA (1 mmol L^{-1}), neutralized, centrifuged, and lyophilized. By this means enzymatic reactions are stopped abruptly and further degradation of metabolites prevented. Dry frozen extracts can be stored for some weeks. Similar recipes use alcohol or alcohol/HCl mixtures.¹⁶ Lipophilic components can be extracted with methanol/chloroform solutions from the residual pellet after centrifugation.¹⁷ Again the extraction should be done quickly and the isolated lipids kept cold. Lipid extracts reflect cell specific variations in the phospholipid composition of different cell types.¹⁸ Also lipophilic drugs, which are retained within the cellular membranes, reappear in the lipophilic extract.

Signal intensities obtained from extracts sometimes do not correlate with those from cells in vivo. Some metabolites

Figure 1 Time course of in situ ^{15}N labeling in the green alga *Chlorella fusca* using a 20 mmol L^{-1} glutamate pulse. The sample was illuminated and bubbled with 95% $\text{N}_2/5\%$ CO_2 . Signals assigned to α -amino groups of amino acids, alanine, glutamate, and γ -amino butyric acid (GABA), δ -ornithine, ϵ -lysine, or polyamine were detected. The external reference standard was urea. The signal from the $\alpha\text{-NH}_3$ of glutamate was positive in the beginning, i.e. showed a NOE, underwent zero transition, and became negative

seen in extracts may be partly or completely invisible in vivo because they are immobilized and/or associated with macromolecules. Lower intensity in extract spectra may be due to losses during extraction by enzyme reactions, chemical degradation, or instability against acids.¹⁹

The peak assignment of extract spectra can be done in different ways: simply by comparison with chemical shift reference lists (^1H ,²⁰ ^{13}C ,²¹ ^{31}P ²²), by spiking the extract solution with the authentic reference compound, by pH titration, by complexation with metal ions, or by de novo assignment of a metabolite within the extract solution by NMR¹³ or by enzymatic transformation.²³ A very efficient way of an in situ assignment is gradient selected inverse multi-quantum coherence (MQC) spectroscopy.²⁴ Figure 2 gives an example where magnetization is transferred frequency-selectively from proton

Figure 2 Pulse sequence for a gradient selected (gs) 2D HSQC TOCSY experiment with long range editing (e.g. Willker et al.²⁴) Spectrum (a) shows the 1D proton spectrum of a cell medium from C6 glioma cells fed with ^{13}C -labeled glucose. Spectrum (b) depicts the row for $1\text{-}^{13}\text{C-}\beta\text{-D-glucose}$ from the gs HSQC TOCSY spectrum. The H-1 signal is positive, the other protons have negative signal intensity

to C-1 of $\beta\text{-D-glucose}$ and back to the proton domain followed by a TOCSY transfer revealing the complete spectrum of $\beta\text{-glucose}$. By this means it is possible to identify one individual compound in a complex mixture without interference from others.

Numerous publications have appeared on cell extracts in the past 15 years. These are beyond the scope of this short survey, but many are covered in excellent reviews.¹⁻⁶ Cell extracts are still the method of choice for sensitive and anchorage-dependent primary cells or cells with demanding growth conditions like brain cells, i.e. neurons, astrocytes, and oligodendrocytes.²⁵⁻²⁷ Figure 3 compares the ^1H NMR spectra of primary rat neurons and astrocytes. Neurons exclusively exhibit *N*-acetylaspargate in NMR-detectable amounts as a neuron specific marker molecule, whereas astrocytes contain myo-inositol as a cell specific marker.

2.2 Cell Suspensions

The simplest way to comply with the constraint of a high density of viable cells within the receiver coil of an NMR probe is to use cell suspensions in the NMR tube. In

Figure 3 ^1H NMR spectra of (a) primary glia cells and (b) primary neurons from rat. Abbreviations are for valine (Val), leucine (Leu), lactate (Lac), alanine (Ala), acetate (Ac), *N*-acetylaspartate (NAA), glutamate (Glu), glutamine (Gln), glutamate/glutamine (Glx), aspartate (Asp), creatine/phosphocreatine (Cr/PCr), choline-containing metabolites (Cho), taurine (Tau), hypotaurine (HTau), glycine (Gly), and myo-inositol (Ins), isoleucine (Ile)

order to maintain the sample under physiological conditions during the measurement, it is necessary to provide a sufficient nutrient and oxygen supply, to remove waste products, to control extracellular pH and sample temperature, to prevent cell sedimentation, and to provide adequate illumination in the case of photoautotrophic cells. It is not possible to meet all these requirements for cell suspensions, at least not for long time periods. Nevertheless, photoautotrophic plant cells can be kept viable in NMR tubes for many hours.

Sedimentation is prevented if the cells are bubbled with air, oxygen, carbogen (95% O_2 /5% CO_2), nitrogen, or argon. This defines at the same time the oxidative state of the cell system and buffers the medium if gas mixtures with carbon dioxide are used. As gas bubbles spoil the B_0 homogeneity within the sensitive volume, the gas flow has to be triggered by the spectrometer to allow time-shared data acquisition and bubbling.^{28,29} If bubbling is not satisfactory, an airlift system driving the medium around above the transmitter coil is an alternative approach.^{30–32} Foaming, which occurs at high gas flow rates, also has to be avoided.³² Alternatively, a mechanical stirrer has been used to prevent sedimentation.^{33,34}

To keep the cells in a defined kinetic state the sample temperature has to be controlled. This is particularly important if proton decoupling and illumination are used simultaneously. Hence, temperature is monitored by a thermocouple or thermometer placed above the coil within the tube. Alternatively, the temperature can be measured by NMR with ethylene glycol.³⁵ The temperature is normally maintained at 37 °C for mammalian cells or ambient temperature for others; it may be advantageous to lower the temperature to 4 °C to slow down the chemical kinetics and to extend the viability of densely packed cell suspensions.

A severe shortcoming of cell suspensions is the lack of a continuous nutrient supply and the removal of waste products.

Figure 4 Illumination and aeration system mounted in an NMR tube. (A) Gas inlet tubes; (B) optical cable; (C) glass tube containing D_2O standard; (D) a Teflon cone for light reflection; (E) star-shaped centering device; and (F) cell suspension. The loss of sensitive volume due to the illumination tube amounts to 25% of the sample volume. (Reproduced by permission of Academic Press from Callies et al.⁴⁰)

Large cells can be locked between two perforated Teflon discs, while the medium circulates with low pressure.³⁶ In a similar manner, a nylon mesh filter may surround the cell suspension.³⁷

Photosynthetic studies by *in vivo* NMR spectroscopy require an apparatus to illuminate the cell suspension within the spectrometer. The illumination has to yield a high enough light intensity and be homogeneously distributed within the sample. Usually the light energy of a powerful light bulb is transferred with a light pipe to the cell suspension.^{38–40} Bubbling with gas prevents shading of parts of the cell population and the radiation damage caused by high light intensities. IR components are filtered between the light source and the light pipe. An efficient light distribution is achieved (Figure 4) if the end of the light pipe is connected to a conical piece of Teflon to scatter the light.⁴⁰ This arrangement induces no further line broadening. The yield for photosynthesis *in situ* in the NMR spectrometer reaches about 50% of that attained for the same number of cells under standard culture conditions.

A particular concern of proton NMR of cells is the intense extra- and intracellular water signal, which has to be suppressed. Different strategies have been used to overcome this problem,^{41,42} i.e. only the frequency region of interest is excited, while the water is left out, or the water magnetization is zeroed (saturated) before data acquisition starts, or multiple quantum filter (MQF) techniques are used, or the water contribution is removed by numerical methods.

2.2.1 Cell Organelles

To trace back individual parts of the cellular metabolism, isolated cell organelles have been examined by NMR. The first study⁴³ on isolated mitochondria and later publications^{44,45} used suspensions of mitochondria. Immediately after preparation they are suspended with medium and transferred to the NMR instrument. Oxygen or carbogen is bubbled through the sample. Viability is controlled in a parallel bath with an oxygen electrode. The high mitochondrial protein concentration was suspected to make part of ATP and Pi invisible.⁴³ However, extra- and intramitochondrial ATP can be discriminated by chelating extramitochondrial ATP with additional magnesium.⁴⁴ Detailed information on mitochondrial tricarboxylic acid (TCA) cycle reactions may be obtained by ¹³C NMR.⁴⁵ Chloroplasts obtained from spinach leaves have also been used in NMR investigations.⁴⁶ Immediately utilized after preparation, they showed, however, little more than a Pi resonance. Studies with chromatophore preparations from photoautotrophic bacteria have been more successful; here not only measurements of pH shifts, but also rates of photophosphorylation could be determined.⁴⁷ Vacuoles have been isolated and used for ³¹P NMR studies on cellular pH regulation.⁴⁸

2.2.2 Perfused Microorganisms

Because of their small size, up to 10¹¹ cells per mL are necessary to obtain acceptable spectra. Cell suspensions are used for short data acquisitions as described in Section 2.2, whereas the entrapment techniques are applied for longer periods. In addition, special flow systems have been designed where the suspension is recirculated.

2.3 Perfused Cells

The problem of maintaining the viability of a dense cell population for a longer period of time (hours and days) has been solved in several ways based on the principle of immobilizing or entrapping cells to allow sufficient perfusion in the NMR tube. As these techniques have been reviewed elsewhere (see *Cells and Cell Systems MRS*), they are only listed here for completeness.^{2,4,5} Cells are grown on microcarrier beads,^{49,50} entrapped in a gel matrix of agarose,⁵¹ or in a basement membrane gel named Matrigel,^{2,4} or in alginate gel beads.⁵² Various subtle techniques use semipermeable hollow fibers to separate cells from flowing medium⁵³ (see also *Bioreactors and Perfusion*). Another approach uses Nylon mesh to support cells.⁵⁴ Advantages and disadvantages of the various methods have been reviewed previously.⁴

3 APPLICATIONS

3.1 General

Historically, in vivo NMR began with studies of red blood cells^{55,56}—a cell type widely available and of only modest experimental demands. Later on Shulman and co-workers started to exploit the biochemical potential of NMR in anaerobic cells (bacteria,⁵⁷ yeast⁵⁸) and aerobic mammalian

cells (liver cells,⁵⁹ tumor cells⁶⁰). This had a strong impact on the use of NMR as a noninvasive biochemical tool to monitor the cellular metabolism with or without arbitrarily set constraints. In the following, only a few selected topics will briefly mentioned. Further applications are compiled in recent reviews.^{1–6,61}

3.1.1 pH Measurement

As the intracellular pH is tightly regulated (pH homeostasis), deviations from the normal value may be induced to study mechanisms of pH regulation.⁶² Different Pi signals indicate subcellular compartments with different pH, i.e. cytosol, vacuoles,⁴⁸ chloroplasts,⁶³ and chromatophores.⁴⁷

3.1.2 Enzymatic Rates In Vivo

NMR is one of the exceptional techniques for measuring enzyme kinetics noninvasively. Two distinct types of techniques are used depending upon the rate constants. Slow reactions ($k \leq 1 \text{ min}^{-1}$) are measured by recording the peak areas as a function of time, i.e. the time course of glycolysis.⁶⁴ Faster reactions ($k \approx 1 \text{ s}^{-1}$) require spin exchange techniques^{65–68} (i.e. saturation transfer, inversion transfer, 2D chemical exchange spectroscopy (ECSY), ACCORDION spectroscopy). By this means, rate constants and unidirectional fluxes through enzymes have been determined. In general this approach is able to differentiate between two sites (or multisites) of a molecule or molecular fragment. Hence, the technique is also suited to measure membrane transport phenomena provided the chemical shift differs in different sites.⁶⁵

3.2 Mammalian Cells

3.2.1 Energy Metabolism

A domain of ³¹P NMR is the depiction of the energetic status of cells.^{3,5,69} Steady-state concentrations of energy-rich phosphates and/or their ratios are used as an indicator of cell viability. However, the energy charge of cells is very well buffered provided the oxygen and nutrient supply is sufficient. Therefore, in contrast to intact organisms, the energy status will only change after dramatic interference. In this respect the energy status is, amongst other indicators, also used to indicate the toxicity of drugs.

3.2.2 Metabolic Pathways

One of the most intriguing features of NMR is the possibility of monitoring the steady state and dynamics of metabolism. The high abundance isotopes (¹H, ³¹P) are suited to characterize the steady state, whereas low abundance isotopes (¹³C, ¹⁵N) give access to dynamic aspects of steady state metabolism. Two major components of cell metabolism, cytosolic glycolysis and the TCA cycle, have been followed in a pioneering study on hepatocytes.^{70,71} This demonstrates the advantage of NMR using stable isotopes with direct molecular information compared with radioisotopes without immediate molecular information.

Figure 5 ^{13}C NMR spectra of cell extracts from (a) F98 glioma and (b) N1E-115 neuroblastoma obtained after an incubation period of 3 h with 2- ^{13}C -pyruvate. Abbreviations as in Figure 3. The pathways depicted relate to the fate of the ^{13}C label after influx into the TCA cycle via pyruvate dehydrogenase (pdh) or pyruvate carboxylase (pc). Abbreviations are citrate (C), α -ketoglutarate (K), glutamate (G), succinate (S), malate (M), oxaloacetate (O), lactate (Lac), alanine (Ala), phosphoenol pyruvate (PEP), serine (Ser), glycine (Gly). Index number indicates the label position via pc activity or in brackets via pdh activity. (Reproduced by permission of S. Karger AG, Basel from Brand et al.⁷⁴)

Whereas hepatocytes are the almost exclusive cell type in liver, other organs consist of morphologically and metabolically different cells. NMR studies on isolated uniform cell populations are an ideal means to characterize their individual contributions to the integral metabolism of an organ. Various kidney cells are functionally and metabolically different, i.e. proximal tubule cells are capable of gluconeogenesis while

medulla cells are not.⁷² A similar, but even more complex, situation is faced in the brain, where neurons, astrocytes, and oligodendrocytes differ metabolically reflecting their individual duties^{25–27,73,74} (see Figure 5). It should be noted that during maturation⁷⁴ or in the presence of systemic pathologies (e.g. diabetes)⁷⁵ enzymatic fluxes may change. Figure 5 describes the different TCA cycle activities in neurons and glia cells.

Phosphorus-31 NMR revealed novel metabolites of carbohydrate metabolism (sorbitol 3-phosphate, fructose 3-phosphate) in the mammalian lens and erythrocytes.^{76,77} Another expanding field of ^{31}P NMR is phospholipid metabolism^{78,79} which is affected in cells with abnormal proliferation,² but also involved in volume regulation.

3.2.3 Redox Status of Cells

Redox homeostasis may have the highest priority within the hierarchy of intracellular homeostasis, although it might be impossible to monitor all parts of this system simultaneously by NMR. The reconstitution of $\text{NAD}^+/\text{NADP}^+$ can be concluded from the lactate/pyruvate and β -hydroxybutyrate/acetoacetate ratio,⁸⁰ but in other cases the dihydroxyacetone phosphate/glycerol 3-phosphate equilibrium is involved as well.^{81,82} Another approach uses labeled nicotinamide to measure $\text{NAD(P)}^+/\text{NAD(P)H}$ ratios directly.⁸³ A further part of the redox system, glutathione, can be monitored by ^1H NMR.⁸⁴

Figure 6 ^{31}P NMR spectra from (a) F98 glioma cells kept in isotonic Dulbecco's modified Eagle medium (DMEM) medium and (b) for 2 h in a hypotonic DMEM (220 mosmol). Abbreviations are nucleotide triphosphate (NTP), adenosine diphosphate (ADP), phosphocreatine (PCr), diphosphate diester (DPDE), glycerophosphocholine (GPC), glycerophosphoethanolamine (GPE), inorganic phosphate (Pi), phosphocholine (PC), and phosphomonoester (PME). GPE, GPC are no longer present under hypotonic conditions and PC is reduced

3.2.4 Osmoregulation and Cell Volume

Cell swelling is a histopathological concomitant of many pathologies like ischemia, spreading depression, even barbiturate anesthesia, etc. NMR spectroscopy of cells provides experimental tools for various problems: efflux or influx of

ions and organic osmolytes upon osmotic stress (see Figure 6) and following regulatory volume decrease or increase; determination of cell volume; differentiation between extra- and intracellular substances.

Cells will swell (shrink) if they are exposed to a hypo-(hyper-)osmolar medium. Short-term and long-term regulation may be followed invasively by quantitative analysis of extracts,⁸⁵ or noninvasively on perfused cells.⁸⁶ In the latter case, it is necessary to differentiate between extra- and intracellular localization of metabolites. This is achieved if a spin in a particular metabolite has different properties inside and outside the cell.⁴ This may be a different chemical shift because of different pH,⁸⁶ the presence of shift reagents,⁸⁷ different relaxation times, or different diffusion constants.⁴ The latter is more generally applicable in vivo and for each nucleus. The use of pulsed gradient spin echoes by Stejskal and Tanner⁸⁸ makes it possible to distinguish between fast diffusing extracellular metabolites and slow diffusing intracellular ones. By this means it is possible to measure intra- and extracellular diffusion constants, the relative change of cell volume, intra- and extracellular low molecular weight metabolites and their exchange.⁸⁷

The cell volume is determined from the equilibrium distribution of indicator compounds given to the cell sample in a defined concentration. Reporter nuclei are phosphorus,⁹⁰ fluorine,^{91,92} or sodium.^{46,93}

The same approach is chosen to measure the amount of extra- and intracellular sodium, where paramagnetic shift reagents induce a chemical shift change in the extracellular compartment.⁹⁴ Correspondingly, potassium ratios are accessible if potassium is partially substituted by rubidium.⁹⁵ Extracellular sodium may be filtered by a multiple quantum filter.⁹⁶ However, even better suppression is accomplished by a triple quantum filter in the presence of paramagnetic lanthanide shift reagents.⁹⁷

Intracellular calcium is chelated by 5-fluoro BAPTA and recorded by ¹⁹F NMR.⁹⁸ Intracellular magnesium can be assessed either from the exchange-averaged chemical shift of β -ATP (equilibrium between Mg-ATP and ATP)⁹⁹ or again by complexation with a fluorinated chelator.⁹⁸

3.2.5 Tumor Cells

NMR studies on tumor cell lines make up the majority of published papers on cell suspensions and perfused cells.^{4,5,9-12,100} These cells proliferate fast enough to the required biomass and they are an accepted model for the metabolism of primary cells¹⁰¹ in substrate utilization, metabolic pathways, pH, energy status, membrane permeability, etc. Besides the similarity with normal cells, tumor cells are an excellent model for testing the cytotoxicity of cytostatic drugs and their pharmacological effects,^{102,103} biotransformation of drugs,¹⁰⁴⁻¹⁰⁷ metabolic differences between normal and drug-resistant cells,¹⁰⁸ hyperthermia,¹⁰⁹ and radiotherapy.¹¹

Tumor cells have also been used to test the hypothesis that a small cytosolic alkaline shift initiates mitogenic stimulation.^{110,111}

3.2.6 Erythrocytes

Red blood cells are well suited for NMR because of their anaerobic metabolism.^{7,8,112,113} Their intrinsic paramagnetic

susceptibility favors techniques for studying exchange and transport reactions,⁶⁵ cell volume, volume regulation,^{93,94} and water transport.¹¹⁴

3.3 Plant Cells

For the purpose of this review, NMR applications are considered using isolated organelles, protoplasts, cell suspension cultures, unicellular organisms, and, whenever suitable, even tissue cultures and organ fragments of photoautotrophic organisms. There are several recent reviews related to NMR studies that cover aspects of plant cellular metabolism^{3,6,115-117} (see also *Plant Physiology*).

3.3.1 Energy Metabolism

Aspects of photosynthesis have been addressed using NMR techniques. Applying ³¹P NMR, the light-dependent alkalinization of the cell cytoplasm has been repeatedly reported.^{44,118-122} There is, however, a persisting debate as to whether a fraction of detectable Pi in eukaryotic cells might stem from the chloroplast.^{63,121,123-125} NMR work on isolated chloroplasts reveals a strong Pi resonance as almost the only signal from this organelle in vitro.^{46,126} Studies on chromatophore preparations also succeeded in quantifying adenylates with a temporal resolution of 2-3 min.⁴⁷

The energetic status of photoautotrophs is usually investigated with intact cells.^{38,118, 125-128} The partial NMR invisibility of adenylates,¹²⁹ however, does not interfere with a rather consistent picture derivable from time-resolved quantifications of the adenylate energy charge and the phosphorylation potential^{130,131} (Figure 7).

Access to autotrophic CO₂ fixation and reductive carbon metabolism has been gained by analyzing ¹³C scrambling patterns subsequent to carbonate or succinate tracer feeding in sycamore cell suspensions¹³² and in a thermophilic archaebacterium, respectively.¹³³

Figure 7 Phosphorylation potential during a transient from dark-to-light metabolism and vice versa in the cyanobacterium *Synechococcus leopoliensis*. The time resolution was achieved by the block-averaging technique on the basis of single ³¹P spectra resulting from 1300 transients. (Reproduced from Maretzek¹³¹)

Figure 8 Contour plot from ^{31}P spectra from a *Chlorella fusca* suspension during transition from anaerobic to aerobic conditions and vice versa in the dark. The contour plot was generated on the basis of spectra resulting from 200 transients equivalent to 100 s (Offermann et al.²¹⁶)

Energy metabolism during dark respiration has been studied using ^{31}P NMR with algae²⁹ and plant cell suspension cultures (Figure 8).

3.3.2 Nutrient Metabolism

Nitrogen uptake and intracellular distribution have been examined in a marine macroalga¹³⁵ as well as in several higher plant tissues^{136–138} using ^{14}N NMR signal intensities and lineshape analysis.

Routes of nitrogen incorporation into organic compounds have been discussed on the basis of ^{15}N labeling patterns analyzed in extracts,¹³⁹ protoplasts,¹⁴⁰ and in intact cells with the additional application of specific enzyme inhibitors.^{141,142} ^{15}N pulse labeling experiments within the NMR tube using tissue cultures¹³⁷ and cell suspensions,¹⁴³ as well as actively photosynthesizing algae and cyanobacteria,^{14,142,144,145} have elucidated the function of glutamate dehydrogenase in different species and thereby contributed to the understanding of primary ammonium assimilation in plants.

Ammonium assimilation has also been intensively studied in fungi, bacteria, and archaebacteria, and even N_2 fixation has been subject to ^{15}N NMR analysis (see Walter et al.⁶).

Specific aspects of amino acid metabolism have been studied with ^{13}C NMR on suspension cultures.^{146,147} Cross polarization with magic angle spinning (CP MAS and DCP MAS) ^{15}N NMR has been applied to analyze the nitrogen utilization for protein synthesis in tissue cultures.^{148,149}

Phosphorus uptake and distribution between the vacuole and the cytoplasm have been studied in great detail utilizing pH-sensitive ^{31}P resonances. Among the systems studied are isolated vacuoles,^{48,150} cell suspension cultures,^{36,151–153} and algae.^{135,154} NMR data on Pi compartmentation is already used to calibrate other soluble distribution data.¹⁵⁵

Questions on the intracellular localization and function of polyphosphates occurring in lower plants have been addressed using ^{31}P NMR.^{124,154,156–159} Surprisingly, saturation transfer techniques which are well suited for studying the specific enzyme kinetics of phosphate metabolism^{66,160} have not

yet received much attention in investigations on plant cell suspensions.⁶³

3.3.3 Homeostasis and Stress Physiology

Maintaining a regulated internal milieu against variable external conditions is a major task of cells. From the various indicators used to study this physiological effort, NMR work has mainly contributed to the understanding of pH regulation and osmoregulation. Monitoring of cytoplasmic pH is almost routinely performed using pH-sensitive resonances, usually the chemical shift of Pi. Vacuolar pH may also be determined on the basis of Pi,^{48,150} though ^{13}C resonances would be more suitable like the C-1 of malate,¹⁶¹ the C-3 of glycerol 3-phosphate,¹⁶² or the CH_2 -linked carboxyl groups (C-1 + C-5) of citric acid¹⁶³ as this compartment typically shows pH values around 5.5. In any case it should be kept in mind that changes in pH can be recorded more accurately than absolute values which rely heavily on the quality of calibration data.^{3,160}

The effect of the external pH regime on the cytoplasmic pH maintenance has been investigated for cell suspension cultures^{37,134,163} and unicellular algae.^{164–168} Cytoplasmic pH is almost independent of external pH over a range from pH 5.5–8.0. This might, however, be extremely costly in terms of cellular energy requirements.¹⁶⁸ Dependence of the energetic state of cells on the cytoplasmic pH has been reported for various plant cells in response to anaerobiosis,^{29,120,167–170} as well as for light–dark transitions.^{118,119,121,165,166,170}

Detailed ^{31}P NMR work has been carried out to investigate the trans-tonoplast pH gradient and thus the connection between short-term and long-term regulation of cytoplasmic and vacuolar pH.^{48,150,163,171}

Temperature changes,¹⁶⁶ as well as elicitor treatment¹⁷² or pulses of ammonium,^{14,173} have been reported to cause pH shifts in cells within the physiological range.

The effect of salt stress on cytoplasmic pH has been described.^{174–176} Osmoregulation, however, has mainly been addressed by characterizing the type and quantities of low molecular weight organic compounds like glycerol in their function as osmoregulatory solutes. Carbon-13 NMR applied to halotolerant unicellular algae^{174–179} and cyanobacteria^{180–183} have been employed in this research.

Sodium-23 NMR spectroscopy¹⁸⁴ was applied to estimate intracellular sodium content at different external salinity.

Naturally occurring unfavorable conditions have been examined using NMR methods. Relaxation times of water protons were determined to estimate the effects of chilling injury to cultured green cells of lavender.¹⁸⁵ Intracellular free amino acids were observed with ¹⁵N NMR to follow the effect of cellular regreening after a period of nitrogen starvation.¹⁸⁶ Polyphosphate hydrolysis has been studied during the regreening after nitrogen starvation in *Chlorella fusca*¹⁸⁷ and in response to alkaline stress in *Dunaliella salina*.¹⁵⁹ The cascade of events following sucrose deprivation in sycamore cell suspension cultures has been studied in great detail applying ³¹P and ¹³C spectroscopy.^{36,188}

3.3.4 Drug Action

Modes of action of the photosystem-II inhibitors diuron and cyanobacterin, a new natural herbicide, have been compared in a cyanobacterium using ³¹P NMR.¹²⁷ The differences in the response indicated cyanobacterin effect on photosynthetic electron transport through an action on the proton pumping mechanism. The metabolic degradation of glyphosate, an amino acid biosynthesis inhibitor, by *Pseudomonas* sp. has been revealed using ¹³C CP MAS methodology.¹⁸⁹ In vivo accumulation of shikimate after glyphosate application could be demonstrated in sycamore cell suspensions.¹⁹⁰ The difference in susceptibility to glufosinate exposure between a cyanobacterium and a green alga could be explained in terms of an alternative pathway of ammonium assimilation in the green alga as described by ¹⁵N NMR.¹⁹¹

3.4 Microorganisms

Microorganisms, in particular bacteria and fungi, are available in a large variety of different strains obtained either by natural selection or more recently by genetic engineering. Their metabolites are natural resources of biomolecules either with natural structure or tailored molecular properties for pharmaceutical or synthetic purposes. NMR spectra of microorganisms have been recorded from cell suspensions, perfused cells, or with specially designed continuous flow bioreactors^{192–196} (Figure 9) (see also *Bioreactors and Perfusion*). A few reviews on yeast^{64,192} and microorganisms in general^{198,199} have been published.

Because of the dense biomass typically used in bioreactors, it may be necessary to slow down metabolic activity by lowering the temperature to 20–25 °C. Viability is controlled by ³¹P NMR. It should be noted that microorganisms have relatively large subcellular compartments (vacuoles, microbody) with a different pH compared with the cytosol.¹⁹⁸ Visible polyphosphate is located in vacuoles, exchanges Pi with the cytosol and is also used for energy storage.²⁰⁰ Intracellular pH is also an indicator of cell division, fermentation, chemiosmotic hypothesis, and germination.^{64,197} Another intriguing property of NMR is its capability to reveal futile cycles in biochemical reactions (e.g. through phosphoenolpyruvatecarboxykinase and pyruvate dehydrogenase).⁹⁸ Futile cycles are difficult to identify by radioisotope labeling.

Figure 9 Continuous-flow NMR bioreactor (375 mL content). Arrows indicate flow direction caused by a centrifugal pump: 1, magnet bore (89 mm); 2, magnet inner wall; 3, shim coil section without spinner turbine; 4, rf coil section; 5, bioreactor lid; 6, prepolarizing chamber; 7, 10-mm tube; 8, glass support for tube. (Reproduced by permission of Academic Press from de Graaf et al.¹⁹²)

Besides normal substrate utilization,^{64,197,198} stable isotope labeling studies have been used to follow-up the biosynthesis of porphyrins,²⁰¹ of actinomycin D and its amino acid precursors,²⁰² of erythritol,²⁰³ the involvement of cyclic 2,3-diphosphoglycerate in gluconeogenesis in a thermoautotrophic methanobacterium,²⁰⁴ conversion of succinate to 4-hydroxybutyrate,²⁰⁵ and biosynthesis of polyols.²⁰⁶

Time-dependent labeling experiments have been used to measure quantitative fluxes in aerobic and anaerobic glycolysis,¹⁹⁷ glycolytic control during the Pasteur effect,¹⁹⁷ maintenance of redox homeostasis by equal fluxes through glycolysis, and pyruvate synthase during acetate utilization by *C. vinosum*.²⁰⁷ ATPase mutants in *E. coli* strains have been characterized by NMR.⁶⁴

Heat shock treatment of yeast leads to pH disorders²⁰⁸ and in a similar manner so does cold shock.²⁰⁹ Labeled acetate was used to follow-up the failure to initiate sporulation in a mutant of yeast.²¹⁰ Osmotic stress is answered by the synthesis of glycerol to lower the osmotic pressure, causing a transient ATP decrease during this adjustment.²¹¹ By ²³Na NMR it is possible to separate intracellular free sodium from cell-bound sodium.²¹² The energy metabolism of yeast recovers incompletely if active dry yeast is rehydrated at 0 °C compared with 40 °C.²¹³ Glucose degradation in *Zymomonas mobilis* is prevented by ethanol concentrations higher than 10% because phosphoglyceratemutase and enolase are inhibited.²¹⁴ In the same organism, membrane transport and fermentation of various carbohydrates have been studied.²¹⁵

4 CONCLUSIONS AND PERSPECTIVES

NMR spectroscopy is now an accepted biochemical tool for noninvasively studying cellular metabolism and transport. Studies on the most different cells with respect to their types and physiological demands may be carried out. Improvements in NMR hardware and the refinement of cell immobilization and/or perfusion techniques have made it possible to record metabolite concentrations of 100 μ molar with a time resolution of several seconds. An increase in field strength and improved probe design promise further enhancement in sensitivity and/or time resolution. The potential of a dozen different NMR active isotopes, the use of inverse detection, and gradient selection techniques will undoubtedly stimulate many new experiments in the future. The almost free choice to set any biological constraints, the use of transgenic cells or natural mutants, and the possibility of manipulating intercellular interactions of uniform and heterogenous cell populations open many new fields of metabolic and physiological studies. Basic biochemistry and the evaluation of the biotechnological productivity of microorganisms will require NMR methods. Cellular models are important test objects for the genesis and understanding of pathologies.

Finally, it is important that the low sensitivity of NMR spectroscopy is compensated by its nonspecificity in detecting cellular metabolites. The presence of unexpected or new compounds is easily recognized, and their chemical class can be estimated from their chemical shifts.

1 INTRODUCTION

The first folded nucleic acid structure to be studied by NMR was tRNA. In the classic paper by Kearns et al.¹ the first observation of resonance signals from hydrogen bonded imino protons from the base pairs of the tRNA was reported. It was immediately obvious that the spread in chemical shifts of these resonances contained information on the three-dimensional structure of the tRNA. Nearly 25 years later, NMR studies of nucleic acids have finally progressed to the point where complete three-dimensional structures of folded nucleic acids, although still only of molecular weights less than half that of tRNA, can be determined from NMR data. These more recent studies have predominantly been of DNA oligonucleotides, primarily because until recently NMR quantities of RNA oligonucleotides were largely unavailable.

Three major developments have contributed to the study of DNA structure by NMR: (1) the advent of higher field magnets for NMR spectroscopy, (2) the development of multidimensional NMR techniques for the study of macromolecules, and (3) the development of methods for the efficient chemical synthesis of DNA oligonucleotides. The applications of multidimensional NMR to the study of nucleic acids have lagged somewhat behind proteins. For duplex DNA, one problem has been that the three-dimensional structure of B-DNA was already known at the resolution that most protein structures could be determined by NMR. Fine details of the structure of the DNA, i.e. base tilt, twist, etc., present a challenging problem for NMR studies because of the lack of sufficient proton NOEs to define these details unambiguously. Recently, several different types of folded DNA structures have been studied by multidimensional proton NMR spectroscopy. These folded DNA structures are of special interest both for their biological relevance and from the spectroscopic point of view, since the tertiary structure provides extra constraints for the three-dimensional structure determination. In this article, the use of modern NMR techniques in the structure determination of DNA triplexes, quadruplexes, and aptamers is reviewed.

2 DNA TRIPLEXES

Application of modern NMR techniques to the study of DNA triplexes began with a report in *Nature* in 1989 on NMR studies of DNA triplexes formed by d(GAGAGAGA) and d(TCTCTCTC).² At low pH values and in the presence of excess pyrimidine strand, imino and amino proton resonances corresponding to C·G·C and T·A·T base triplets (Figure 1) were observed. These and other triplexes were further described in subsequent publications from several groups. These studies showed conclusively that DNA triplexes with the expected Hoogsteen base pairing of the second pyrimidine strand in the major groove of the Watson–Crick paired duplex were formed. However, it was difficult to characterize these triplexes further because other conformations such as duplex, single strand, and self-complex of the purine strand were also present. In 1990, an NMR study on a single strand of DNA that was designed to fold to form an intramolecular triplex was reported.³ Figure 2 shows the one-dimensional ¹H spectra of the exchangeable imino and cytosine amino proton resonances of this oligonucleotide as a function of pH. Since Hoogsteen pairing of the cytosine residues in the second pyrimidine strand requires protonation at N-3, the triplex structure is favored at low pH. Imino resonances corresponding to six base triplets and one G·C base pair are seen at pH 5, indicating triplex formation. The characteristically high-frequency (low-field) shifted amino resonances from the protonated Cs are also present. The triplex form predominates up to pH 6.5. At pH 7.0 there are about equal amounts of the intramolecular triplex and the partial duplex. Above pH 7.0, the partial duplex predominates. Assignments of the resonances were obtained by analysis of two-dimensional NOESY spectra of the molecule in H₂O. The intramolecular triplex model system has since

Figure 1 Hydrogen bonding of base triplets (a) T·A·T and (b) (C·G·C)

Figure 2 One-dimensional proton NMR spectra of the imino and C amino proton resonances of d(GAGAGAACCCCTTCTCTCTTTCTCTCTT) as a function of pH (left). Illustration of the equilibrium between the folded triplex structure and the partial duplex (right). (Adapted from Sklenář and Feigon³)

been used to characterize a number of triplexes containing other triplets.^{4–9}

Two different classes of triplex have been identified: (1) the pyrimidine motif, in which the third strand is pyrimidines, and binds parallel to the purine strand, forming T·A·T and C·G·C triplexes, and (2) the purine motif, in which the third strand is primarily purines, and binds antiparallel to the Watson–Crick paired purine strand, forming G·G·C and A·A·T or T·A·T triplets. The pyrimidine motif is the best characterized. The base–H-1' region of a NOESY spectrum of a 32-base pyrimidine triplex is shown in Figure 3 to illustrate some of the ¹H spectral characteristics of triplexes.⁴ Three sets of base–deoxyribose H-1' sequential connectivities are observed, corresponding to the three strands of the triplex. These sequential connectivities are consistent with a regular right-handed helical structure. The intramolecular triplex also showed unambiguously that the second pyrimidine strands binds parallel to the purine strand via Hoogsteen

base pairing in the major groove of the DNA. Previous structural information of DNA triplexes was derived from fiber diffraction work on poly(dT·dA·dT).¹⁰ From this work, it was concluded that DNA triplexes were A-DNA-like with C-3'-endo sugar puckers. However, analysis of COSY cross-peak patterns of the H-1'–H-2'/ H-2'' resonances (Figure 4) of the intramolecular triplex indicated that the majority of the deoxyribose conformations are in the C-2'-endo range characteristic of B-DNA.¹¹ Thus, from the NMR data it was concluded that the DNA triplexes were more similar to B-DNA than A-DNA in structure. Intramolecular triplexes have also been used to investigate a number of different mismatch or noncanonical triplets within the pyrimidine motif. In general, the base-pairing scheme was deduced from analysis of the NMR spectra of the exchangeable imino and amino resonances. Further details on the structures were obtained from analysis of the D₂O spectra, and several model structures based on NMR data have been reported.^{4,8,9}

Figure 3 Portion of NOESY spectrum showing the base–H-1' cross peaks of the intramolecular triplex formed from d(AGAGAGAACCCCTCTCTCTTTTCTCTCT). Bases forming the loops are in bold. The sequential connectivities along each of the three strands of the triplex are indicated by solid lines. (Adapted from Macaya et al.⁴)

Purine motif triplexes have been less well studied. This is partially because the conditions for formation of these triplexes are less well established. The base pairing and strand orientation for intramolecular purine motif triplexes were established by the NMR studies of Radhakrishnan and Patel.⁹ In the presence of Li⁺ counterions, intramolecular triplexes containing G·G·C and T·A·T or G·G·C and A·A·T triplets were formed.

3 DNA QUADRUPLEXES

It was established over 30 years that guanosine and its derivatives can hydrogen bond in a tetrameric arrangement to form guanine quartets (Figure 5) (reviewed by Guschlbauer et al.¹²). This hydrogen bonding also seems to be related to the fact that guanosine mono- and oligonucleotides easily form viscous gels in the presence of monovalent cations. This propensity for aggregation in guanine-rich oligonucleotides has limited the structural characterization of guanine-rich DNAs by NMR. Early NMR work on guanosine 5'-phosphate and guanine oligomers investigated the role of specific cations in self-assembly of these gels. These studies provided evidence for formation of tetrameric structures.

The current interest in DNA quadruplexes arose from observations that a variety of DNA oligonucleotides composed of biologically relevant guanine-rich sequences seemed to form some unusual structures in vitro. Guanine-rich sequences are found in immunoglobulin switch regions, telomeres, the dimerization domain of the HIV-1 genome, and other sites in eukaryotic genomes. In several cases, it was proposed that these unusual structures might be quadruplex structures. Much of the recent work on guanine-rich DNAs has focused

Figure 4 Portion of P.COSY spectrum of the intramolecular triplex formed from d(AGAGAGAACCCCTCTCTCTTTTCTCTCT) showing the H-1'–H-2' and H-1'–H-2'' cross peaks. (Adapted from Macaya et al.⁴)

Figure 5 Structure of a guanine quartet

Figure 6 Schematic of the quadruplex structure of Oxy-1.5. (Adapted from J. Feigon, F. W. Smith, R. Macaya, and P. Schultze, 'DNA Quadruplexes: From Telomeres to Aptamers', ed. R. H. Sarma and M. H. Sarma, Adenine Press, Schenectady, NY, 1993, p. 127)

on the structures of DNA oligonucleotides which contain the telomere repeat sequence of various organisms. The first NMR evidence that such oligonucleotides formed an unusual structure was an investigation of oligonucleotides containing the *Tetrahymena* repeat $d(T_2G_4)$.¹³ No assignments were made, but the authors were able to determine that some of the guanine nucleotides were *syn* on the basis of two-dimensional 1H NMR spectra. NMR studies of $d(G_2T_4CG_2)$ and $d(G_2T_5G_2)$ indicated that the guanines were 5'-*syn*-*anti*-3', but the molecularity of the structures formed was not established.^{14,15} In 1992, Smith and Feigon¹⁶ reported NMR studies of two DNA oligonucleotides containing the telomere repeat sequence $d(T_4G_4)$ from *Oxytricha nova*, $d(G_4T_4G_4)$ (Oxy-1.5) and $d(G_4T_4G_4T_4G_4T_4G_4)$ (Oxy-3.5). The oligonucleotides form a symmetrical dimeric (Figure 6) and a unimolecular quadruplex, respectively. Both structures have four guanine quartets formed from nucleotides that alternate *syn* and *anti* along each guanine tract. A model structure of Oxy-1.5 was refined with NOE constraints. This structure was subsequently refined from metric matrix distance geometry derived starting structures. A surprising feature of the solution structure is that the thymines looped diagonally across the end quartets, rather than across an edge. A concurrently published crystal structure of Oxy-1.5 had the thymines looping across a wide groove at each end of the quadruplex.¹⁷ The different solution and crystal structures have been a source of some controversy. The solution structure has since been confirmed by several different

Figure 7 Portion of NOESY spectrum of Oxy-1.5 showing the cross peaks between the base and H-1' proton resonances. Connectivities between pairs of *syn* and *anti* guanines are indicated by solid lines. (Adapted from F. W. Smith and J. Feigon, *Biochemistry*, 1993, **32**, 8682)

methods, and it seems unlikely that it is in error. Another diagonally looped structure has recently been reported for the human telomere repeat oligonucleotide $d[AG_3(T_2AG_3)_3]$.¹⁸ This unimolecular quadruplex has two edge loops at one end of the quadruplex and a diagonal loop at the other end, similar to Oxy-3.5.

Fold-back DNA quadruplexes have several unique 1H NMR spectral features. Each guanine residue involved in quartet formation gives rise to a hydrogen-bonded imino proton resonance. These protons exchange with water unusually slowly and often can be observed long after the sample has been transferred to D_2O . The guanine quartet structure can be identified by a series of NOE cross peaks in NOESY spectra in H_2O between guanine imino, amino, and H-8 protons. Another unusual feature arises from the presence of *syn* nucleotides. This gives rise to a completely different pattern of NOE cross peaks between the base H-8/6 and deoxyribose H-1' than seen for B-DNA, as illustrated for Oxy-1.5 in Figure 7. Since standard sequential assignments are not possible due to a break in connectivities between 5' *anti* and 3' *syn* nucleotides, alternative approaches must be used in making assignments. One useful method is the use of derivatives containing inosine in place of guanine. This allows unambiguous identification of

Figure 8 Three-dimensional structure of the thrombin-binding aptamer. A view into the wide groove is shown. The two guanine quartets are colored green, the conserved thymines that form a T-T base pair are colored yellow, and the non-conserved thymines (top T-G-T loop (bottom) are colored red. The eight best (lowest energy) calculated structures are shown superimposed. (Adapted from Schultze et al.²⁶)

the inosine H-2 resonance, which replaces the guanine amino resonance.

A number of tetrameric quadruplexes have also been solved by NMR. These include quadruplexes formed by d(T₂AG₃), d(T₂G₄),¹⁹ d(TG₄T),²⁰ and r(UG₄U).²¹ These tetrameric quadruplexes have four parallel strands with all *anti* guanine nucleotides.

4 DNA APTAMERS

'Aptamer' is a name coined for DNA or RNA oligonucleotides which have been selected for binding to a specific target molecule from a large pool of oligonucleotides containing a region of random nucleotide sequence.²² The isolation process involves repeated cycles of selection for, and enrichment of, oligonucleotides with an affinity to a specific target, followed by amplification of these sequences using the polymerase chain reaction (PCR). Oligonucleotides with the selected characteristics, i.e. binding to a specific molecule, are finally identified through cloning and sequencing. The potential of these methods for the development of oligonucleotide-based therapeutics has excited much interest in the pharmaceutical industry.

Aptamers present a special challenge both for NMR and from the nucleic acid structural point of view, since new folding motifs may appear from the *in vitro* selection. To date, the structure of only one (DNA) aptamer has been solved. DNA oligonucleotides were selected for the ability to bind to and inhibit thrombin, an essential protein in the blood-clotting cascade.²³ The particular thrombin-binding aptamer which has been studied by NMR has the sequence d(GGTTGGTGTGGTTGG). The overall fold of the molecule

was determined independently by Wang et al.²⁴ and Macaya and co-workers^{25,26} using two-dimensional ¹H methods. The thrombin-binding aptamer forms a unimolecular quadruplex containing two guanine quartets. These are connected by two T-T loops across the narrow grooves at one end and a T-G-T loop across a wide groove at the other end of the mini-quadruple helix (Figure 8). The thrombin aptamer structure has been refined from metrix matrix distance geometry-generated starting structures using restrained molecular dynamics and direct NOE refinement.

1 INTRODUCTION

There has been a long history of studying DNA with NMR techniques, most focusing on the proton and phosphorus resonances. In the earliest days, as with all biopolymers, resonance assignments were very difficult to establish, and only qualitative correlations with other types of data could be developed. However, with the development of higher field and two-dimensional spectroscopy came the ability to assign resonances rigorously and make more detailed studies of structure. Here studies of three forms of DNA, A, B, and Z, are described, with some historical perspective.

The original descriptors of 'A' and 'B' DNA came from fiber X-ray diffraction studies in which it was noted that the diffraction pattern changed in certain characteristic ways upon changes in hydration (controlled through relative humidity of the surroundings of the fiber) and salt.¹ At moderate levels of salt, the ordered pattern which formed first with increasing hydration (at least 4 water molecules per nucleotide for a double-helical form) was called the A-form, which converted spontaneously to B-form at higher hydration (about 20 water molecules per nucleotide when hydration is complete). These patterns formed for natural DNA and, with relatively little variation, for essentially all double stranded, complementary (G with C, and A with T) synthetic polymer DNAs. Of course such fiber diffraction data played a critical role in the development of the correct hydrogen bonded, duplex structure of DNA proposed by Watson and Crick.² Both of these forms correspond to right-handed helices, with slightly different repeats and local structure. Fairly detailed models were developed from the fiber data, eventually extended with single crystal data. The A- and B-forms differ in position of base pairs with respect to the helix axis, the tilt of the base pairs, and in the sugar conformation.

Later a new structure was found in single crystals grown of alternating (C-G)₃ sequences, in which the helix was left-handed and the repeating unit was a C-G repeat rather than a single nucleotide. This form was termed Z-DNA.³ In addition to the change in handedness of the helix, there were also a number of other differences in local conformation relative to the A- and B-forms. A number of different experiments,⁴ including NMR and circular dichroism, indicated that this form was also found in solution at very

high salt concentrations or with addition of salt and alcohol, although these data were insufficient to characterize the form of the DNA unambiguously before the crystal structure was solved. Drawings of models for eight base pair sequences of the B-, A-, and Z-forms of DNA are shown in Figure 1. This highlights the fact that there are dramatic differences in overall helix morphology, in spite of the fact that the base pairing is the same in each case.

Although diffraction data provided information about fibers, and later single crystals of oligomers, an important question which remained was how well these crystalline forms represented what was present in solution. With quite a number of short oligomers (6 to 10 residues in length), crystal structures indicated that the DNA was in the A-conformation. Circular dichroism and qualitative NMR studies, however, seemed to indicate that the same oligomers were in the B-form in solution. An interesting case is a section of DNA recognized by the transcription factor TFIID. Since TFIID binds to both DNA and RNA, it was speculated (supported by some digestion and methylation experiments) that the DNA was A-form, at least when recognized.⁵ Further support came from the fact that a nine base pair sequence containing this site crystallized in the A-form.⁶ However, solution NMR experiments demonstrated clearly that this sequence is the unexceptional B-form DNA in solution.⁷ It now appears that different parts of TFIID recognize DNA and RNA.

A major contribution of NMR has been to provide a method through which detailed characterization of the solution structure of DNA can be achieved. The solution conditions can be adjusted reasonably to approximate the conditions which the DNA experiences in vivo and hence may be better for understanding functions and interactions of the DNA than conditions used for crystallization. There are features of DNA which make structure determination more difficult than for typical globular proteins⁸ (see *Nucleic Acid Structures in Solution: Sequence Dependence*). However when care is used (see *Relaxation Matrix Refinement of Nucleic Acids*), important structural information (especially about local structure) may be obtained.

2 BASIC FEATURES OF NMR SPECTRA OF DNA

The structures of the Watson-Crick base pairs of the four common natural nucleotides are shown in Figure 2. The protons can be logically grouped as those attached to nitrogen (exchangeable, disappearing rapidly in D₂O as solvent) and those attached to carbon (nonexchangeable), which are conveniently well dispersed in terms of their chemical shifts (see *Nucleic Acids: Chemical Shifts*). The imino protons of G and T are convenient markers of hydrogen bonding since they occur one per base pair, and are strongly shifted to high frequency, typically being found in the 12–14 ppm range. If these protons are exposed to solvent water the exchange rate is sufficient to broaden them significantly (see *Nucleic Acids: Base Stacking and Base Pairing Interactions*). However, when hydrogen bonded, the rate is dramatically slowed and the protons can be seen as sharp resonances, as in the high frequency (downfield) part of Figure 3. The amino protons of C, G, and A resonate in the 6.5–9 ppm range, overlapping the H-8 and H-6 aromatic protons of the bases. The A and G resonances are frequently very broad due to rotational

Figure 1 Eight base pair segments of the B-, A-, and Z-forms of DNA. Although the base pairing is the same in each, there are differences in stacking, backbone conformation and handedness of the helix (A- and B-forms right-handed, Z-form left-handed). Only the heavy atoms (C, N, O, and P) are shown

exchange between the hydrogen bonded and exposed positions. The peaks associated with the cytosine amino protons are slightly broadened, but not as greatly as those of A and G. The anomeric sugar protons, H-1', and cytosine H-5 aromatic proton resonances overlap in the 5.5–6.5 ppm region. Sugar H-3' resonances fall near the water resonance (4.5–5.2 ppm), with the H-4', H-5', and H-5'' resonances slightly further to low frequency (upfield) extending to about 4 ppm. The H-2' and H-2'' resonances fall furthest to low frequency of the sugar resonances, at 1.8–3 ppm. At the low frequency end of the spectrum, the thymine methyl protons are found, in the 1.5–2 ppm region. Each of these regions is easy to identify in the spectrum shown in Figure 3.

3 ASSIGNMENTS OF DNA SPECTRA

The key to full interpretation of DNA solution structures is having complete resonance assignments. This can be done with different approaches, one based upon combining information from ^1H – ^1H and ^1H – ^{31}P couplings in COSY and HETCOR type experiments, and the other based upon ^1H COSY and NOESY data. The general ideas for these sequential assignment approaches were first developed for proteins,⁹ but were extended to DNA by several workers at about the same time. In the coupling approach,¹⁰ groups of coupled spins within each sugar are identified from the COSY (or TOCSY) data (up to seven if all can be resolved, numbered with respect to the attached carbon atom 1' through 5' as in Figure 1). Neighboring sugars are identified by the fact that their sugar protons (H-3', H-4', or H-5', 5'') are

coupled to the same phosphate's ^{31}P resonance, identified in the HETCOR spectrum (see *Nucleic Acids: Phosphorus-31 NMR*). Although this is a very good approach in principle,

Figure 2 The structures of Watson–Crick base pairs, showing the numbering of some of the atoms indicated for reference to the text. Purines G and A are to the left, the pyrimidines C and T to the right. Hydrogen bonds are indicated by the dashed lines

Figure 3 The one-dimensional ^1H NMR spectrum of the DNA oligomer CGCAAAAGGC:CGTTTTCGC. The spectrum was acquired in H_2O solution with presaturation of the solvent water resonance. Protons resonating in various regions of the spectrum are indicated. *The amino resonances of cytosines

with no assumptions required about the structure, there are several technical problems: the heteronuclear couplings are rather small, and hence cross peaks become weak as the molecular weight increases; the couplings to the phosphate occur to the sugar H-3' on one side, and the sugar H-4', H-5', and H-5'' on the other side, all of which occur in rather crowded regions; and, finally, the phosphate resonances are often also rather poorly dispersed in chemical shift. This last problem can be avoided by just using the ^{31}P to relay the proton couplings; however, crowding in the spectrum of the sugar protons is still a significant problem.

In the second approach,¹¹ the COSY (or TOCSY) data again serve to identify coupled groups of protons. In addition to those within the sugars, the H-5–H-6 pairing for each cytosine base, and the H-6– CH_3 pairing for each thymine can be seen. Guanine and adenine each give rise to singlets for the H-8 (G and A) and H-2 (A) resonances. NOESY cross peaks then provide information about the proximity of protons, and hence about which bases are neighbors in the sequence. It is a fortunate fact that most nucleic acid structures (and certainly the A-, B-, and Z-forms) are stabilized by base stacking. Hence the residues which are in closest proximity are neighbors in the primary sequence.

In the A- and B-forms the stacking is regular (about the same at each base step), and hence a regular pattern of cross peaks is seen in the NOESY spectrum. A section of a B-form helix is shown in Figure 4, in which lines are drawn from each aromatic proton to both its own sugar H-1' and H-2',2'', and

also to the neighboring H-1' and H-2',2''. The distances are all within the range which gives rise to NOESY peaks (about 0.4 nm). Spin diffusion pathways contribute to the intensities of some of the peaks, but this does not confuse the assignments.

Figure 4 A four base segment of one strand of a B-DNA duplex is shown as a stereo pair (sequence 5'-ATTC-3' running bottom to top). The connectivities which can be seen in different regions of the spectrum are indicated by dotted and dashed lines. Aromatic hydrogens are solid black, H-1 protons are gray and others connected by lines are H-2', H-2'' protons. All hydrogens are indicated by circles

For steps with pyrimidines (C and T) there is an additional connectivity from the H-5 or CH₃ to the preceding aromatic proton, which is useful for verifying connectivities.

The expansions of these two NOESY regions are shown for a DNA duplex with 11 base pairs in Figure 5. The DNA sequence is not self-complementary, and hence each strand leads to a separate set of connectivities. Any degeneracies in resonances are resolved by identifying the type of base (T, C, or purine) from the COSY data, and knowing that the final assignments have to include all resonances and follow the known primary sequence of the DNA.

The patterns of the NOEs which are seen during the assignment in fact confirm that the DNA is in a right-handed helix. When the intensities of the NOEs within the sugars are analyzed, their patterns can be used to determine the sugar conformation as well (though this is often more easily done with couplings, as described below). Observation of both types of pattern for a particular DNA is a strong indication that the DNA is in a B-type conformation. The assignment process and qualitative NOE analysis are fairly simple for DNAs of up to about 20 base pairs (40 nucleotides). In fact, almost all duplex DNAs examined in water solution have been found to be in the B-form. For larger DNAs, more extensive coupling information from double quantum spectra is needed, but with the collection of many data sets it has even been possible to assign a 64 nucleotide Holiday junction,¹² comprising four DNA duplexes joined into a cross. This corresponds to a molecular weight of about 21 kDa.

There have been few studies of A-form DNA in solution.¹³ This is primarily because dehydration is required (such as can be accomplished by addition of ethanol to the solution), but then the solubility of the DNA is very low. There are indications that polyvalent cations can also drive the B → A transition under conditions where NMR is practical.¹⁴ In RNA the extra 2'-OH relative to DNA changes the conformational preference to the A-form under normal conditions. The pattern which would be expected for A-form DNA is actually rather similar to B-form, since both are right-handed helices, with base stacking. However, there are some differences in distances, making the sequential connectivities through H-1' weaker. But, by using moderately long mixing times spin diffusion strengthens these, and the assignment pathways can be followed very much as in the B-form.

The patterns of the NOEs for Z-form DNA are quite different from those of the A- and B-forms due to the dinucleotide repeat, and the different stacking of the bases.¹⁵ One dramatic difference is that the relative orientation of the sugar and purine bases [G residues in the classical (C-G)_n sequences which take on the (Z) conformation] are *syn* rather than *anti*, as occurs in B-DNA. This reduces the H-1'–H-8 distance from about 0.37 nm (*anti*) to 0.24 nm (*syn*), giving much stronger and thus very characteristic H-8–H-1' NOESY peaks. In steps from G to C there are a number of aromatic proton to sugar distances which are short enough to give rise to NOESY peaks, but in C to G steps the only protons which are close are the sugar H-4', H-5', and H-5'' protons. Since these occur in very crowded regions of the spectrum, they are not very useful for sequential assignments.

In an early study of (m⁵C-G)₃, in which the methyl group on cytosine makes the transition occur at lower salt or added alcohol, advantage was taken of the ability to control the equilibrium.¹⁴ A sample was titrated with methanol until about

equal amounts of the B- (assigned with the sequential method described above) and Z-forms were present. Although the kinetics of this transition are slow, it was possible to use a very long mixing time in the NOESY experiment (1.4 s) to detect exchange cross peaks between the two conformers. Since the B-form was assigned, the assignments of the Z-form aromatic protons were then determined directly. The sugar resonances were then assigned primarily using intraresidue NOEs. It is interesting to note that the conformation of the phosphates in Z-DNA also alternate, which gives rise to a grouping in the ³¹P chemical shift of the GpC versus CpG type phosphates.

The same principles were applied to a DNA oligomer *CG*CGAT*CG*CG, where *C is Br⁵-C, which like the methyl modification facilitates the transition.¹⁶ This sequence violates the alternating C-G (and even purine–pyrimidine) which favors Z-DNA formation, yet with addition of 3 M NaCl in 33% methanol clear changes in the spectrum were seen. It was found that a Z type conformation was found, with all of the Cs and the A in the *anti* conformation, but the Gs and the T were *syn*. The phosphates appear much as expected for an 'ordinary' Z-form oligomer. A similar phosphate pattern was also seen for longer polymers of d(A-m⁵C)-d(G-T) at 5.4 M salt and 65°C, again indicating a Z type conformation.¹⁷

4 COUPLINGS AND CONFORMATION

Although the overall helical character of DNA is not strongly dependent on the local conformation at each nucleotide, there are correlations of local conformation with overall structure which makes identifiers of local conformation valuable. One of the most commonly used is the conformation of the sugar. The five-membered deoxyribose ring occurring in each residue of a DNA can take on many different conformations,¹ often called puckers. However, each of these has one or two atoms out of the plane of the ring (*endo* or *exo*, depending upon whether it is on the side from which the base and C-5' protrude or the opposite side). The conformation of the sugar then really only has two free parameters: which atom(s) are out of the plane, and by how far. If the sugar ring is considered as a circle, then the atom lying out of the plane can also be described through an angle, known as the 'pseudorotation angle.' The distance the atom(s) are out of the plane is called the 'pucker amplitude'. Sugars with puckers near the top of the circle are also referred to as north, while those near the bottom are south.

B-Form DNAs typically have sugars near the C-2' *endo* (south) conformation. Of course as the conformation of the sugar changes, so do the dihedral angles between protons and hence the coupling constants. Therefore, couplings provide a sensitive probe of the sugar conformation (see *Vicinal Coupling Constants and Conformation of Biomolecules*), which can be determined from a number of variations of the COSY experiment.¹⁸ The general pattern of which cross peaks are seen can often be a good qualitative indicator, requiring no detailed analysis. In the C-2' *endo* conformation the coupling of H-1' to both H-2' and H-2'' is large enough to give a clear cross peak. However, the H-3' coupling to H-2' is very small, while H-3' to H-2'' is moderate. Therefore, only the H-3' to H-2'' cross peak is seen. Since the H-1', H-2', and H-2'' resonances are usually well resolved, this pattern of peaks can be identified fairly easily.

Figure 5 (a) The aromatic to H-1' cross peak region of a NOESY spectrum of the DNA oligomer CGCAAATTGGC:GCCAATTGCG. The spectrum was recorded in D₂O solution with a mixing time of 200 ms. (—, - - -) The tracing of assignments along the two strands are shown with solid and dashed lines. The peaks which are intrasidue are labeled with the identity of the residue; sequential peaks are not labeled. The unconnected horizontal lines indicate connectivities involving the cytosine H-5 atoms. *Peaks and unconnected vertical lines involve the adenosine H-2 aromatic and H-1' atoms from both strands. These are not used for assignments, and are typically seen only in A-rich sequences. (b) The aromatic to H-2', H-2'' region of the same NOESY spectrum as in (a). The sequential connectivities are again indicated by solid and dashed lines. The intrasidue aromatic H-2' peaks are labeled. The unconnected horizontal lines at the top are connectivities involving the thymine methyl protons

In the A-form conformation the typical sugar pucker is C-3' *endo* (north). In this case the H-1' to H-2' coupling is very small, and the H-1' to H-2'' coupling is moderate, so that only the latter cross peak is seen. On the other hand, the H-3' couplings to both H-2' and H-2'' are large enough to give clear cross peaks, again making a qualitative determination of the sugar conformation easy.

In Z-DNA there is an alternation of sugar conformation, with the G residues C-3' *endo* and the C residues C-2' *endo*. Of course, with residues assigned by NOEs it is possible to recognize this alternating conformation feature as another marker of Z-DNA.

5 MOTION AND HYDRATION

Solid state NMR has also played a role in understanding DNA structure and dynamics (for methods see *Protein Dynamics from Solid State NMR*). As noted above, in solid samples the interconversion between A- and B-DNA can be controlled by hydration. Studies of the ³¹P chemical shift anisotropy lineshape, and relaxation time have provided information about the range of motions of the phosphate in different forms of DNA.¹⁹ It was found that narrowing occurred gradually with increasing hydration, with plateaus seen in the regions corresponding to A- and B-DNA. However, as hydration increased, there was a continuous increase in the amplitude of motion of the phosphate. Later, the same features were examined using selectively deuterated bases²⁰ and sugars,²¹ with the quadrupole coupling tensor as the probe. Again, increasing hydration increased the amplitude of motion, although to a lesser extent than was seen for the phosphate. Ordered DNAs, such as fibers, can also be used for studies of hydration.²²

Studies of hydration in solution have also been carried out, the first one being reported in 1954.²³ The broadening of the water resonance by DNA indicated interaction between them. Much later, site specific interactions were detected by using NOE data, with which more tightly bound water could be distinguished from loose surface water.²⁴ More studies of different sequences will certainly follow.

6 SUMMARY

More details on many aspects of structural and dynamic studies of DNA are given in other chapters of this Encyclopedia, as indicated at various points above. In this section the basics of DNA conformation have been described, together with the information about how resonances are assigned and what markers of conformational features exist in the NMR data. Local conformational features may be determined fairly directly; however, more global features are determined by complex combinations of different types of data. Because of the indirect nature of the structure analysis, and the fact that only local distances are determined from NOE data, one must be careful and critical about global features of the structures. In spite of the difficulties, NMR has been very useful in understanding solution structures of DNAs and the implications that the structures have for biological activity.

1 INTRODUCTION

The thermodynamic and molecular properties of polyelectrolytes in solution depend strongly on the amount of added salt. In particular, the conformational transitions and binding interactions of nucleic acids in aqueous solution exhibit pronounced dependences on salt concentration, which result from Coulombic interactions between electrolyte ions and the phosphate charges on the nucleic acid (for early but comprehensive reviews see Manning¹ and Record et al.²). Information about ion–nucleic acid interactions is therefore a crucial component of any quantitative description of the conformational transitions of nucleic acids and of their interactions with other biopolymers. On the molecular level, the measurement of NMR relaxation rates for the quadrupolar nuclei of alkali and alkaline earth ions has emerged as a useful experimental method for studying the equilibrium and dynamic aspects of cations interacting with DNA. Several reviews are available.^{3–6} The present article is focused primarily on the use of NMR relaxation rates of quadrupolar nuclei to investigate the extent of association of one or more types of cation with DNA in solutions dilute enough to be isotropic.

Fundamentals of the NMR relaxation processes of quadrupolar ions, the physical variables, and the types of information that can be gained by measuring them, are reviewed in the remainder of this section. In the second section we discuss the two state model, which provides a basis for analyzing the concentration dependence of relaxation rates in order to investigate the distribution(s) of cations surrounding DNA. Experimental studies using the NMR relaxation rates of quadrupolar nuclei to investigate cation–DNA interactions are reviewed in the third section, and the fourth summarizes some less common NMR approaches and alternatives to NMR as a means of probing various aspects of cation–DNA interactions.

1.1 Fundamentals of the Quadrupolar Relaxation Process

All the inorganic (K^+ , Na^+ , Mg^{2+} , and Ca^{2+}) and organic (polyamines) cations present at significant concentrations in vivo, as well as all other alkali and alkaline earth metal

ions and quaternary ammonium ions, have isotopes with nuclear spins (I) greater than $\frac{1}{2}$. Specifically, $I = 1$ for ^{14}N , $\frac{3}{2}$ for ^{23}Na and ^{39}K , $\frac{5}{2}$ for ^{25}Mg , and $\frac{7}{2}$ for ^{43}Ca . The nuclei of these cations have quadrupole moments which dominate the relaxation of the nuclear magnetic dipole by coupling with the fluctuating electric field gradients (EFGs) produced by diffusional motions in the local environment. In aqueous solution the quadrupolar relaxation of monatomic ions such as ^{23}Na is due to intermolecular field gradients caused by surrounding ions and water dipoles, in contrast to the (generally much stronger) intramolecular field gradient experienced by a quadrupolar nucleus involved in covalent bonding (such as ^{14}N in CN^-).

In dilute solutions of biopolymers, the NMR relaxation processes of quadrupolar cations are in the ‘extreme narrowing’ limit when $\omega_0\tau_c \ll 1$, where ω_0 is the nuclear Larmor frequency and τ_c is the (mean) correlation time for the fluctuations of the EFG at the nucleus. Under conditions of extreme narrowing (at low enough magnetic fields and/or high enough temperature) the longitudinal and transverse NMR relaxation processes both decay as single exponential functions of time with the same rate constant:⁷

$$R_1 = R_2 = \frac{3}{40} \left[\frac{(2I+3)}{I^2(2I-1)} \right] \left[1 + \frac{\eta^2}{3} \right] \chi^2 \tau_c \quad (1)$$

where R_1 and R_2 are the longitudinal and transverse relaxation rates, respectively; I is the nuclear spin quantum number; χ is the quadrupole coupling constant, which is the product of (eq) , the mean square average local EFG and (eQ) , the nuclear quadrupole moment; and η is the asymmetry parameter, which is generally zero for nuclei that experience intermolecular field gradients in isotropic environments. In the limit of extreme narrowing, for any type of quadrupolar nucleus the NMR relaxation process (longitudinal or transverse) is a single exponential with a rate constant that does not depend on ω_0 . The Fourier-transformed NMR lineshape is a single Lorentzian with a linewidth at half height $\Delta\nu_{\frac{1}{2}}$ (in hertz), from which the transverse relaxation rate constant can be determined directly with the expression $R_2 = \pi \Delta\nu_{\frac{1}{2}}$.

When $\omega_0\tau_c$ is not negligible in comparison to unity, the transverse and longitudinal relaxation processes are no longer equivalent, and the functional forms of their time dependences depend critically on the magnitude of I , as well as that of $\omega_0\tau_c$. Outside the limit of extreme narrowing, the dependence of R_1 and of R_2 on χ^2 and τ_c becomes more complicated than in equation (1), and in some situations explicit analytic expressions for the relaxation processes cannot be given. When $\omega_0\tau_c$ is much greater than unity, the quadrupolar relaxation is in the slow motion regime, where various manifestations of quadrupolar splitting may be observed.⁸ At sufficiently high concentrations (high fields and/or low temperatures), slow motion effects may be manifested by quadrupolar nuclei in solutions of nucleic acids. Some studies of these effects are considered in Section 3.4, but the rest of this article is concerned with NMR relaxation subject to the condition of ‘motional narrowing’ (that is, outside the ‘slow motion’ limit).

Outside the limit of extreme narrowing for nuclei with spin $I = 1$ (e.g. ^{14}N) both the transverse and the longitudinal relaxation process are single exponential functions with different characteristic time constants at all field strengths.⁷ For nuclei with spin $I = \frac{3}{2}$ (e.g. ^{23}Na or ^{39}K), an analogous

situation exists only up to $\omega_0\tau_c \approx 1.5$,⁹ beyond which the transverse and (at least in principle) the longitudinal relaxation process become biexponential, each with two distinct rate constants. For this case the general relaxation equation may be found in Hubbard's original article.⁷ The Fourier transformation of this biexponential transverse relaxation process yields a spectrum in the frequency domain that consists of two Lorentzians whose peaks coincide or are separated by a (generally) small dynamic shift. The linewidth at halfheight of this bi-Lorentzian spectrum bears no simple relationship to either of the two relaxation rate constants. Evaluation of these can be accomplished only by deconvoluting the full lineshape. For nuclei with $I > \frac{3}{2}$ the time dependence of the magnetization cannot be expressed in a closed form outside the extreme narrowing limit.⁷ However, as shown by Westlund and Wennerström,¹⁰ analytic expressions for the Fourier-transformed spectrum in the frequency domain can be derived for nuclei with $I > \frac{3}{2}$. A recent example of the use of these equations to analyze the lineshape of ^{25}Mg in DNA solutions has been reported by Wright and Lerner.¹¹

When the NMR relaxation processes of quadrupolar nuclei are outside the limit of extreme narrowing at a given composition and temperature, a study of the dependence of the relaxation processes on magnetic field strength can in favorable cases permit separate evaluation of the factors χ^2 and τ_c that comprise R_1 and R_2 . Such an analysis is generally based on an assumed form of the correlation function that describes the modulation of the local EFG by various kinds of diffusional molecular motions. Often the quadrupolar correlation function is taken to be a single exponential, the simplest form that may be physically realistic. However, in the case of DNA solutions, Leyte and co-workers¹² have definitively shown that the quadrupolar correlation function is biexponential, consisting of a linear superposition of contributions from a 'slow' process (outside the limit of extreme narrowing at typical field strengths) and a 'fast' process that may be due primarily to interactions with water dipoles.

Correlation times and quadrupolar coupling constants can be evaluated by various methods in addition to determining the field dependence of relaxation rate(s). For nuclei having $I = 1$, or $I = \frac{3}{2}$ provided $\omega_0\tau_c < 1.5$, separate determinations of R_1 and R_2 at one field strength may suffice to evaluate τ_c if the correlation function is a single exponential. Recently, more sophisticated methods have been developed to detect multiple quantum transitions that contain information about the spectral densities from which the form(s) of the correlation function(s) can be investigated.^{13,14}

1.2 Overview of the Relaxation Characteristics of Quadrupolar Nuclei

The ease with which quadrupolar lineshapes and relaxation rates can be measured for cations in solutions containing polyions depends primarily on the natural abundance of the NMR active isotope and on its gyromagnetic ratio γ . One of the most common intracellular cations is K^+ . Although the NMR nucleus ^{39}K ($I = \frac{3}{2}$) has a substantial natural abundance (93.1%), its small magnetogyric ratio makes it relatively difficult to detect accurately. At magnetic field strengths presently available, however, ^{39}K can be studied accurately at concentration levels as low as 1 mM, which has enabled some

direct observations of intracellular ^{39}K .¹⁵ In most intracellular environments, Na^+ is present at much lower concentration than K^+ , but since ^{23}Na ($I = \frac{3}{2}$) has 100% natural abundance and its gyromagnetic ratio is more than five times larger than that of ^{39}K , it is more readily detectable at a given concentration. Other quadrupolar cations found in vivo, such as ^{25}Mg ($I = \frac{5}{2}$) and ^{43}Ca ($I = \frac{7}{2}$), have both low natural isotopic abundances (10% and 0.145%, respectively) and low magnetogyric ratios. (For ^{43}Ca the exceptionally small quadrupole moment further complicates accurate measurements of its NMR relaxation rates.)

Quantitative as well as qualitative information on cation-DNA interactions has been obtained by analyzing the dependence of cation relaxation rates on cation concentration, DNA phosphate concentration, temperature, and magnetic field strength. Since ^{23}Na is the most 'sensitive' (in the NMR context) of the quadrupolar nuclei typically found in vivo, it has been the most extensively investigated. ^{23}Na is used either as a direct probe of sodium-DNA interactions, or in competition experiments, as an indirect probe of the interactions of other monovalent and oligovalent cations (including Mg^{2+} , Ca^{2+} , and polyamines) with DNA.^{12,16-35}

Under most conditions for quadrupolar nuclei other than ^{23}Na there are serious difficulties arising from low NMR sensitivity and/or complications associated with describing the relaxation processes. Increasing the field strength tends to alleviate problems of low NMR sensitivity, but if the field strength is high enough to take the relaxation out of the extreme narrowing limit, considerable complexity in the relaxation process can result for nuclei having $I > \frac{3}{2}$. Nevertheless, the following quadrupolar nuclei have been used as informative NMR probes: the alkali metal nuclei ^{39}K , ^{87}Rb , ^{133}Cs , and ^7Li ;^{30,31,36-38} the alkaline earth nuclei ^{43}Ca and ^{25}Mg ;^{11,21, 39-44} ^{59}Co in $\text{Co}(\text{NH}_3)_6^{3+}$;^{20,21,45,75} and ^{14}N in polyamines.^{28,29}

Figure 1 summarizes results of competitive titrations of NaDNA ($[\text{P}] = 15 \text{ mM}$; $[\text{Na}^+]/[\text{P}] = 1.6$) with salts of various

Figure 1 Representative plots of ^{23}Na NMR linewidths ($\Delta\nu_{1/2}$) in calf thymus NaDNA solutions (0.015 M in DNA phosphate) as a function of the ratio of equivalents of added salt to DNA phosphate (eq/P). (Reproduced with permission of the National Academy of Sciences, USA, from Bleam et al.¹⁷)

cations.¹⁷ In this study (at relatively low magnetic field) the lineshapes are in each case single Lorentzians, implying the ‘extreme narrowing’ limit. Therefore, transverse relaxation rates, R_2 can be obtained directly from measurements of linewidths at half height ($\Delta\nu_{\frac{1}{2}}$). The initial ^{23}Na linewidth (36 Hz for $\Delta\nu_{\frac{1}{2}}$, or 113 s^{-1} for the transverse relaxation rate) is significantly enhanced compared with the linewidth of Na^+ in aqueous NaCl solution without DNA (approximately 6 Hz or 18 s^{-1}). As additional cations (either Na^+ or competitive cations) are added to the NaDNA solution, the observed ^{23}Na linewidth decreases and eventually approaches the linewidth of Na^+ in a NaCl solution. Quantitative information regarding cation–DNA interactions is obtainable from analysis of these titrations of NaDNA with Na^+ and other cations. In particular, the noncompetitive Na^+ titration indicates that the extent of accumulation of Na^+ in the vicinity of DNA is relatively insensitive to NaCl concentration. The competitive titrations indicate that the order of cation affinities for DNA is $\text{Mg}^{2+} > \text{NH}_4^+ > \text{Na}^+ > \text{Bu}_4\text{N}^+$. The extent of Na^+ accumulation and the relative affinities of other cations have been quantified on the basis of model assumptions, as described in the following section.

2 THE COMPOSITION DEPENDENCE OF QUADRUPOLEAR RELAXATION RATES

2.1 Fundamentals of the Two State Model for Quadrupolar NMR Relaxation Rates

In systems where two or more magnetically distinguishable states are accessible to nuclei whose rate(s) of exchange among these states greatly exceed(s) their NMR relaxation rates in any state, the observable NMR relaxation rate is the population-weighted average of the relaxation rates characteristic of the individual states. Although there can be complicating effects for quadrupolar nuclei due to the interplay of dynamic frequency shifts with the exchange and relaxation rates,¹⁰ a decrease in relaxation rates with increasing temperature often suffices to demonstrate that quadrupolar nuclei are in fast exchange on the NMR timescale. The NMR relaxation process may begin to manifest effects of ‘slow exchange’, especially for cations of charge higher than one and in solvents other than pure water. In the (rare) situations where the NMR relaxation is governed entirely by slow exchange, the observed NMR relaxation rate constant is related simply to the kinetic rate constant for the exchange process. With a few exceptions,^{11,39} in this article we consider only systems where the effects of slow exchange (if any) can be neglected for the purpose of analyzing the concentration dependence of NMR relaxation rates.

From the standpoint of describing the NMR relaxation of rapidly exchanging cations in a nucleic acid solution, they can be classified as either ‘bound’ or ‘free’ by their proximity to a molecule of nucleic acid. The ‘free’ state consists of those ions that are far enough removed from the vicinity of any DNA molecule that their relaxation rates are not significantly perturbed by the presence of DNA in solution. Generally, R_F^M is equated to the relaxation rate observed in

an aqueous solution containing no polyelectrolyte. The term ‘bound’, defined empirically by the effects of DNA on the quadrupolar relaxation rates (χ and/or τ_c) of nearby nuclei, does not necessarily imply a specifically localized long-lived complex with any particular site on DNA. The two state model has been used to analyze relaxation data for many types of cation in DNA solutions (^{23}Na , ^{39}K , ^{87}Rb , ^{133}Cs , and ^{14}N in hexamethonium and ^{43}Ca).^{16,18,20,21,26,29,32,36,37}

For nuclei undergoing rapid exchange between these ‘bound’ and ‘free’ states, the observed relaxation rate can be described as a population-weighted average of the relaxation rates in the two states:

$$R_{\text{obs}}^M = p_F^M R_F^M + p_B^M R_B^M \quad (2)$$

where R_{obs}^M denotes the observed transverse (R_2) or longitudinal (R_1) relaxation rate of the cationic nucleus M; R_B^M is the (average) relaxation rate characteristic of the fraction of the total population of M^{x+} ions that are in the ‘bound’ state (p_B^M); and R_F^M characterizes the fraction of nuclei in the ‘free’ state (p_F^M). Equation (2) can be rewritten to emphasize the dependence of R_{obs}^M on the extent of binding of the ion bearing the nucleus whose relaxation rate is being observed:

$$R_{\text{obs}}^M = R_F^M + p_B^M (R_B^M - R_F^M) \quad (3)$$

It proves convenient to express p_B^M as $[P]r_M/z[\text{M}^{x+}]$, where r_M is the fraction of the DNA phosphates that are, in effect, neutralized by the complement of M that are bound by the NMR criterion. Introducing this definition into equation (3) yields:

$$R_{\text{obs}}^M = R_F^M + r_M (R_B^M - R_F^M) \frac{[P]}{x[\text{M}^{x+}]} \quad (4)$$

The effects of proximity to the surface of DNA on the relaxation of individual cationic nuclei may be manifested as an enhancement of their coupling constant(s) and/or their correlation time(s). In general, the bound relaxation R_B may be an average over a diverse set of environments that are, in principle, magnetically distinguishable. However, R_B often appears to be invariant to changes in the composition of the solution. Thus, in this situation consideration of a single (average) bound state suffices, and detailed information about the distribution of nuclei among the various bound states that differ magnetically cannot be elicited from the composition dependence of quadrupolar NMR relaxation rates. In fact, an unequivocal separation of even the single averaged quantity R_B from composition variables is rarely possible. Moreover, there is as yet no completely reliable a priori theoretical means of predicting absolute values of R_B under typical conditions of interest, though progress toward this important goal continues to be made.⁴⁶ Despite the limitations imposed at present by these experimental and theoretical considerations, much has been learned from studies of the composition dependences of quadrupolar NMR relaxation rates. Studies of this type are the primary concern of this article.

2.2 Noncompetitive Titrations

In solutions containing only one type of counterion M^{x+} , titrations of DNA with M^{x+} yield plots of R_{obs}^M versus $[P]/z[M^{x+}]$ that, within uncertainty limits, are linear with an extrapolated y intercept equal to the free relaxation rate R_F^M . The product $r_M(R_B^M - R_F^M)$ must therefore be constant. Insufficient information is available from any noncompetitive titration to determine the individual parameters r_M and R_B^M . These parameters must either remain individually constant, or vary in a compensatory manner, as $[P]/z[M^{x+}]$ changes. The latter alternative is made less likely by the observation of linear noncompetitive titration plots for a variety of cationic nuclei (including both univalent and divalent ions) in DNA solutions.^{12,16,18,19,27,32,36,37} The physical factors that could impart a concentration dependence to r and R_B are interrelated, and for univalent ions some degree of compensation may be expected on theoretical grounds.^{47,48}

2.3 Competitive Titrations

Competitive titrations can be analyzed, on the basis of some additional assumptions, in order to separate the terms r_M and R_B from the product $r_M(R_B^M - R_F^M)$ which can be evaluated from a noncompetitive titration. In DNA solutions containing more than one type of cation, the ion exchange process can be analyzed using the two state model by introduction of two additional composition-independent parameters: an ion-exchange affinity coefficient D_m , and a stoichiometric coefficient n .^{16,17,29} The dimensionless ion-exchange parameter D_m is defined as:

$$D_m = (p_B^L)(p_F^M)^n / (p_F^L)(p_B^M)^n \quad (5)$$

where p_B^L is the fraction of competitive ions (L^{z+}) that are in the 'bound' state, and $p_F^L = 1 - p_B^L$. In comparing two different competitors, the one having the larger value of D_m as defined by equation (5) has the larger affinity (relative to M) for DNA. By assumption, the stoichiometric coefficient, n in equation (5) also characterizes the cumulative displacement of M^{x+} by L^{z+} ; this is expressed as:

$$n = (r_M^0[P] - [M^{x+}]_B) / [L^{z+}]_B \quad (6)$$

The larger the value of n , the more effective is L^{z+} in displacing M^{x+} from DNA. To prevent depleting the total amount of positive charge due to small mobile ions near DNA, n must be less than or equal to $[z/x]$. Provided that the binding of the competitive ion does not cause any significant long range alterations in the charge density of the nucleic acid, this upper bound is plausible.

According to the two state model for the competitive titration, the observed relaxation rate can be expressed by combining equations (2) and (6):

$$R_{\text{obs}}^M = R_F^M + (r_M^0 - n p_B^L [L^{z+}] / [P]) (R_B^M - R_F^M) \frac{[P]}{[M^{x+}]} \quad (7)$$

where $p_B^L = [L^{z+}]_B / [L^{z+}]$ is implicitly defined in equation (5),¹⁸ and r_M^0 is the extent of association of M^{x+} (usually

Na^+) in the absence of L^{z+} . The superscript 'o' designates the initial state before the addition of another type of cation.

In analyzing a complete titration curve according to the equations specified above, a constraint can be placed on the number of parameters by fitting the initial linear region, which in most cases ranges over $0 < [L^{z+}]/[P] < 0.1$. The quotient r_M^0/n can be determined as the ratio of the slope to the intercept of the initial linear portion of the titration curve (if initially $p_B^L = 1$). Then, r_M^0 can be calculated assuming $n = z$, which is the maximum number of M^{x+} that can be displaced by the competitive cation M^{x+} , without depleting the number of positive charges in the vicinity of the polyion.

2.4 Physical Interpretation of the Bound State

Although the two state model stipulates that each observable NMR relaxation rate is a population-weighted average of 'bound' and 'free' states, no particular physical interpretation of these states is implied by the model. Both polyelectrolyte theory and mass action models of ligand-DNA binding have been used to interpret the 'bound' and 'free' states.

The mass action model describes the exchange of cations between occupied and unoccupied 'sites' on the polyion as an equilibrium:

where $[M_F]$ and $[S_F]$ are the concentrations of the 'free' ions and available 'sites', respectively, and $[MS]$ is the concentration of occupied 'sites' ('bound' ions). The equilibrium quotient pertaining to equation (8) is defined as:

$$K_{\text{eq}} = \frac{[MS]}{[M_F][S_F]} \quad (9)$$

The mass action equation [equation (9)], in conjunction with the two state model has been solved either by estimating $[MS]$ at each point of a titration and using an iterative procedure to solve for K_{eq} or by taking the limit of $[S_T] \ll [M_T]$ to simplify the solution for K_{eq} .^{30,49}

Other analytical approaches used to describe the 'bound' and 'free' states are given by two theories applicable to cylindrical polyelectrolytes: Manning's counterion condensation (CC) model, and the Poisson-Boltzmann (PB) equation. Both of these theoretical approaches specify a dimensionless parameter to define the average axial charge density:

$$\xi = e^2 / \epsilon k T b \quad (10)$$

where ϵ is the dielectric constant of pure solvent, b is the average axial distance between phosphate groups, e is the electronic charge, k is the Boltzmann constant, and T is the absolute temperature.

Manning's counterion condensation theory, applied to a polyion with $\xi > 1$, predicts that the concentration of ions within a well-defined annular volume surrounding the polyion is high and only weakly variable with salt concentration.⁵⁰ Specifically, for a DNA solution containing only univalent cations, the extent of condensation binding per phosphate is predicted to be $1 - \xi^{-1}$ (0.76 for helical NaDNA in H_2O at 25°C). The concentration of 'territorially bound' counterions

in the condensation layer is predicted to be independent of changes in the bulk salt concentration up to about 0.1 M. For bulk electrolyte concentrations above 0.1 M, the local surface concentration increases as the bulk salt concentration increases up to about 1 M, where they approach each other.

PB theory assumes that the local ion gradients surrounding a cylindrically symmetric highly charged polyion can be described as a continuous function given by a Boltzmann factor in the mean electrostatic potential energy (see for example, Fuoss et al.⁵¹). According to solutions of the cylindrical PB equation, a high (>2 M) local concentration of cations exists at the surface of double-helical DNA, and decreases radially to the bulk electrolyte concentration. The volume of solution surrounding DNA does not completely exclude co-ions (as in the CC model), but their local concentration is predicted to be much lower than in the bulk solution. PB theory predicts that the concentration of cations at the surface of the DNA polyanion is buffered against changes in the bulk electrolyte concentration, but that the local concentrations of both cations and anions increase significantly with increasing electrolyte concentration in the typical experimental range.⁵²

Both CC and PB theories are based on the same model of the polyelectrolyte solution, but incorporate different assumptions and approximations. Monte Carlo (MC) simulations provide a means of testing the various model assumptions.^{52–55} For a simple ‘primitive’ model, which represents the DNA as a rigid uniformly charged impenetrable cylinder and the cations as hard spheres, MC simulations have been used to calculate the radial distribution functions of small ions.^{52–55} For monatomic ions with hydrated radii in the usual (~0.3 nm) range, MC simulations yield ion distributions which agree with the corresponding predictions of PB theory.

The relative affinities of the univalent cations for DNA that have been quantified by means of ²³Na NMR¹⁷ have been accounted for theoretically by means of MC simulations.⁵⁵ For divalent alkaline earth ions, interactions with DNA in addition to the Coulombic interactions described by the primitive model appear necessary to account for the initial region of a competitive titration curve, but for some methylated polyamines the agreement with theoretical prediction is satisfactory.²⁷ Neither PB calculations nor MC simulations based on the standard primitive model are capable of accounting for the remarkable constancy of r that has been inferred from ²³Na NMR measurements (and is a central feature of the CC theory). A more complete discussion of the implications of quadrupolar NMR measurements for theoretical descriptions of counterion radial distributions surrounding DNA has been given in a recent review.⁵⁶

3 SURVEY OF EXPERIMENTAL RESULTS ON CATION–DNA INTERACTIONS

3.1 Noncompetitive Titrations

3.1.1 Nucleic Acids Titrated with Na⁺

Since ²³Na is the most accurately detectable of the quadrupolar cationic nuclei, it has been the probe chosen in the majority of quadrupolar NMR studies. The earliest investigation of the interactions of Na⁺ with nucleic

acids was performed by James and Noggle,⁴⁹ who studied counterion–yeast tRNA interactions and observed a linear relationship [as expected by rearrangement of equation (4)] between $(R_{\text{obs}}^{\text{Na}} - R_F^{\text{Na}})^{-1}$ and $[\text{Na}^+]$, until aggregation of the RNA occurred.⁴⁹ Reuben et al.³⁰ performed ²³Na relaxation experiments using sonicated salmon testes DNA, and observed a linear relationship between the observed relaxation rate and $[\text{Na}^+]_B/[\text{Na}^+]$. $[\text{Na}^+]_B$ was estimated for each point of the noncompetitive titration.³⁰ Both studies used the mass action model to determine equilibrium binding constants and ‘bound’ relaxation rates (R_B^{Na}). For Na–DNA ($[P] = 26.2 \text{ mM}$), the equilibrium binding constant (K_{eq}) was determined to be 91 M^{-1} ; for Na–RNA ($10\text{--}2.46 \text{ mg ml}^{-1}$ RNA) equilibrium constants ranged from 195 to 457 M^{-1} . The two state model [equation (4)] was used to calculate the ‘bound’ relaxation rates: for DNA, R_B^{Na} was approximately 170 s^{-1} ; for RNA, R_B^{Na} ranged from 202 to 227 s^{-1} . With these values of R_B^{Na} and the corresponding reported values of K_{eq} , $[P]$, $[\text{Na}^+]$, and r_{Na} in equation (4) can be evaluated. Values of r_{Na} calculated in this way from the study of Reuben et al.³⁰ lie in the range $0.91\text{--}0.96$, close to total neutralization of the DNA phosphates. This value is significantly higher than that predicted by Manning’s CC model⁵⁰ and still higher than the range of values that have been predicted by solving the PB equation or MC simulations.⁵³ For tRNA the data of James and Noggle⁴⁴ yield values of r_{Na} in the range $0.74\text{--}0.98$ for the experimental range of salt concentrations ($50\text{--}500 \text{ mM}$).

Titration of polymeric (sonicated) NaDNA with NaCl have been performed at several different field strengths, temperatures, and initial ratios of Na⁺ to DNA phosphate.^{12,16–18,20,21,23–25,29,32} In these studies, $R_{1,\text{obs}}^{\text{Na}}$ (or $R_{2,\text{obs}}^{\text{Na}}$) was plotted against $[P]/[\text{Na}^+]$ (the ratio of the total DNA phosphate concentration to the total sodium ion concentration) and analyzed by the two state model (equation (4)).

Table 1 presents values of the parameters of the noncompetitive two state model obtained from plots of observed R_1 and R_2 versus $[P]/[\text{Na}^+]$ for a variety of polymeric samples of native DNA (sonicated calf thymus, *Micrococcus lysodeikticus*, *Clostridium perfringens*, and phage T7). These noncompetitive titrations of NaDNA with ²³Na include all published data (in the indicated temperature range)^{17,25,27,29} and unpublished work from the authors’ laboratory.³² Because the relaxation rate is dependent on temperature, the data in Table 1 represent only those data obtained in the temperature range $23\text{--}27^\circ\text{C}$. No explicit temperature corrections were applied. In papers where the authors did not report a number for the slope $[(r_{\text{Na}}(R_B - R_F))]$ or intercept (R_F), it was extracted for the table by analyzing the reported data. Values of R_B were estimated using a value for r_{Na} of 0.6 , as was estimated in competitive titrations of NaDNA with Mg^{2+} and $\text{Co}(\text{NH}_3)_6^{3+}$.^{19,27,28}

Examination of the slopes and intercepts in Table 1 indicates the following generalizations.

1. R_F typically is within the uncertainty of the relaxation rate of Na⁺ in the absence of DNA ($18.0 \pm 1 \text{ s}^{-1}$) at 25°C .⁵⁷ Thus, it is reasonable to use the relaxation rate of Na⁺ in aqueous solution containing only NaCl as an estimate of the relaxation rate in the ‘free’ state. The values for R_F are also field independent, so that the relaxation of nuclei in the ‘free’ state must be in the ‘extreme narrowing’ limit.
2. The slope, $r_{\text{Na}}(R_B - R_F)$ decreases with increasing field strength. Since R_F and r_{Na} (the fraction of phosphates neutralized by Na⁺) are both independent of field strength,

the relaxation of nuclei in the ‘bound’ state must be outside of the extreme narrowing limit.

3. A comparison of values reported for $r_{\text{Na}}(R_B - R_F)$ or R_B at a single field strength (Table 1) indicates little consistency for either parameter. In addition to the range of temperatures (23–27°C), this variability may be due to the variety in sample conditions (i.e. buffered versus unbuffered) used in previous investigations.
4. As discussed previously, linearity is observed when $R_{\text{obs}}^{\text{Na}}$ is plotted as a function of $[P]/[\text{Na}^+]$, which indicates that either $r_{\text{Na}}(R_B - R_F)$ is constant or that the two individual parameters, r_{Na} and R_B are variable but effectively compensate each other. Although the simplest inference is that $r_{\text{Na}}(R_B - R_F)$ is constant,^{16, 18, 25, 29} direct compensation of r_{Na} and R_B has not been disproved and may be indicated theoretically under some conditions.^{46, 47}

3.1.2 MDNA Titrated with M^{x+} (Cations other than Na⁺)

Several noncompetitive DNA–cation titration studies have been performed using NMR nuclei other than ²³Na; ³⁹K with KDNA,³⁶ ⁸⁷Rb with RbDNA,³⁰ and ¹⁴N with HexDNA (Hex²⁺ is a divalent methylated polyamine [hexamethonium, (CH₃)₃N⁺–(CH₂)₄–N⁺(CH₃)₃]).²⁹ These studies reached conclusions analogous to those reported for ²³Na NMR relaxation studies with Na–DNA: the observed relaxation rate is a linear function of the concentration ratio $[P]/[M^{x+}]$.

3.2 Competitive Titrations

3.2.1 MDNA Titration with L^{z+} Monitored by ²³Na NMR

In addition to Na–DNA titrations with NaCl, various organic (NH₄⁺, polyamines, and tetraethyl- or tetrabutylammonium), alkali metal (Cs⁺, Li⁺ and K⁺), alkaline

earth (Mg²⁺ and Ca²⁺), and the inorganic cationic complex Co(NH₃)₆³⁺ have been used in competitive titrations with NaDNA. From these titrations, Anderson et al.¹⁶ and Bleam et al.¹⁷ have shown that the relative affinities of univalent cations for DNA are NH₄⁺ > Cs⁺ > K⁺ > Li⁺ > Na⁺ > Et₄N⁺ > Bu₄N⁺. In general, univalent ions have a smaller affinity for DNA than do the divalent cations (Mg²⁺, Ca²⁺ or polyamines). Within the group of divalent cations, the alkaline earth metal ions, in general, have greater affinities for DNA than do polyamines.^{6, 36} Divalent Mg²⁺ and putrescine(2+) have lower affinities for DNA than do the trivalent spermidine(3+) and cobalt hexamine, Co(NH₃)₆³⁺.³⁶ As in the case of the divalent cations, the affinity of the spherical inorganic trivalent cation Co(NH₃)₆³⁺ is higher than that of the elongated, low-charge-density spermidine(3+).

3.2.2 DNA Titrations Monitored by NMR of Multivalent Ions

Reimarrson et al.⁴² demonstrated the feasibility of studying the interactions of Mg²⁺ and Ca²⁺ with DNA by measuring the ²⁵Mg and ⁴³Ca NMR linewidths, even though both nuclei have unfavorable NMR characteristics (low natural abundance and sensitivity). This initial study was done at very low magnetic field strength and (of necessity) high concentrations of ²⁵Mg and ⁴³Ca counterions. For both ²⁵Mg and ⁴³Ca, the temperature dependence of the linewidths was judged inconsistent with nuclei in fast exchange.

NMR studies following the initial work of Reimarrson et al.⁴² have yielded complicated and somewhat contradictory results. Competitive titration studies by Rose et al.^{43, 44} implied that titration of MgDNA with mono- or divalent counterions (Na⁺, Ca²⁺, Zn²⁺, Ni²⁺, and Hg²⁺) did not result in the displacement of all of the ‘bound’ Mg²⁺ ions, as inferred by the inability to reduce the ²⁵Mg linewidth to 2.5 Hz, its value in the absence of DNA. This result was interpreted as evidence

for at least two different types of 'bound' population. However, more recently, Braunlin and co-workers^{20,21} have performed competitive titrations with Ca^{2+} and MgDNA at smaller ratios of $[\text{Mg}^{2+}]/[\text{P}]$ than those investigated by Rose et al.⁴⁴ The more recent titrations gave no evidence for a 'bound' ^{25}Mg population that could not be displaced by excess Ca^{2+} .

The possibility that various cations may have specific interactions with nucleic acids has been investigated for DNA of differing GC content. In these studies ^{23}Na ,^{26,45} ^{59}Co in $\text{Co}(\text{NH}_3)_6^{3+}$,^{58,59} and ^{43}Ca ⁴⁵ relaxation rates, and ^{59}Co and ^{43}Ca chemical shifts,^{45,58} were measured in titration studies of *Micrococcus lysodeikticus* (72% GC), *Escherichia coli* (41% GC), calf thymus (39% GC), *Clostridium perfringens* (31% GC), and oligonucleotides varying in GC content.⁵⁹ No discernible dependence on GC content was observed in the ^{23}Na studies, a finding which is in agreement with the long-standing inference that (at least under typical experimental conditions in vitro) there is no NMR evidence for the existence of site binding of Na^+ to native DNA.¹⁶ Use of the mass action model to describe the accumulation of sodium ions in the vicinity of DNA must therefore be considered a parameterization. By contrast, in the studies utilizing ^{59}Co and ^{43}Ca , large differences in both chemical shifts and relaxation rates were measured as a function of GC content. Thus, these higher valent cations exhibit some degree of specificity in their interactions with DNA.

3.3 Other NMR Studies of Interactions of Divalent Ions with DNA

Rose et al.^{43,44} performed temperature dependent studies on the ^{25}Mg linewidth, which yielded results similar to the initial observations of Reimarrson et al.⁴² The ^{25}Mg linewidths exhibited a gradual increase with increasing temperature, which is inconsistent with fast exchange between two sites. This study was also first to report a non-Lorentzian lineshape for ^{25}Mg in a Mg–DNA system, which was hypothesized to result from a residual first-order nuclear quadrupole interaction.

Berggren et al.³⁹ carried out the first quantitative analysis of the temperature dependence of the linewidths and longitudinal relaxation rates for ^{25}Mg in Mg–DNA systems. In this study the authors fitted the temperature dependences to an isotropic two-site discrete exchange model based on that developed by Westlund and Wennerström.¹⁰ This model, which can be used to describe quadrupolar systems undergoing (not necessarily rapid) exchange between two classes of sites, also takes into account the dynamic frequency shifts between each of the three transitions for a spin- $\frac{5}{2}$ nucleus. With this model, Berggren et al.³⁹ could not fit quantitatively the temperature dependences of both the linewidths and the longitudinal relaxation rates using a single set of parameters, although the qualitative trends in both data sets at higher temperatures could be reproduced. On the basis of qualitative trends, Berggren et al.³⁹ concluded that the Mg–DNA system could be modeled as a two state system in which the exchange rate between 'bound' and 'free' populations was of the order of milliseconds.

Wright and Lerner¹¹ performed a frequency-dependence study of ^{25}Mg linewidths in Mg–DNA systems in which the Westlund and Wennerström¹⁰ isotropic two state exchange

model was used to fit the field dependence of the lineshapes. The results of this study demonstrated that this model could not reproduce the experimental field dependence of the lineshapes. More complicated models, including, for example, nonisotropic relaxation in the bound state, multiple correlation times for the bound state and/or multiple bound populations, must therefore be required to describe the composition dependence of ^{25}Mg in solutions of Mg–DNA. This study was also the first to report a co-ion dependence for the ^{25}Mg relaxation rates in DNA solution. Specifically, the temperature dependence of the linewidth varies with the nature of the co-ion (SO_4^{2-} , Cl^- , and ClO_4^-) (the last measured by Berggren et al.)³⁹ The co-ion dependence demonstrates that exchange rates, relaxation rates, or other parameters determined in a particular Mg^{2+} –co-ion–DNA system cannot necessarily be generalized to Mg–DNA interactions in solutions containing other types of co-ion.

3.4 NMR Studies of Ion–DNA Interactions in Concentrated Solution

The preceding sections have dealt with the use of quadrupolar NMR relaxation to study interactions of cations with DNA in dilute solution (1–30 mM). More recently, quadrupolar NMR has also been applied to concentrated solutions ($\geq 450 \text{ mg ml}^{-1}$).^{14,33,34} Strzelecka and Rill^{33,34} reported ^{23}Na NMR relaxation experiments on concentrated 147 base pair DNA samples from nucleosome core particles at several sodium ion concentrations (0.01, 0.1, and 1 M) and Groot et al.¹⁴ used chicken erythrocyte nucleosome core DNA. The observed R_1 increases as the DNA concentration is increased ($10\text{--}290 \text{ mg ml}^{-1}$ DNA), whereas R_1 decreases as the temperature increases ($20\text{--}60^\circ\text{C}$). As the DNA concentration is increased, the solution changes phase from isotropic to anisotropic, and the slope of the R_1 versus $[\text{P}]/[\text{Na}^+]$ plot becomes steeper. The authors propose that the abrupt increase in the slope is due to an increase in the number of counterions in the vicinity of DNA and an increase in the average electric field gradient experienced by the 'bound' ions. Increasing the DNA concentration and the temperature affects the distance between the DNA and the cholesteric pitch (i.e. as the DNA concentration increases the distance between DNA molecules decreases).

Several authors have showed the feasibility of ^7Li and ^{133}Cs NMR on oriented DNA fibers.^{13,31,60–62} Some of these ^7Li and ^{133}Cs NMR investigations of oriented DNA fibers involved the use of multiple quantum coherence experiments, which provide information about the dynamics of the cation.^{61,62} In addition, two-dimensional experiments (two-dimensional quadrupole echo and two-dimensional spin echo) were used to measure homogenous linewidths, which can be evaluated in terms of fast and slow motional correlation times for the ions in the presence of DNA.

Schultz et al.³¹ used both single pulse and double quantum filtered pulse sequences to determine the quadrupolar splitting for macroscopically oriented fibers of NaDNA, LiDNA, and CsDNA. In a highly concentrated DNA solution, the ^{23}Na signal is split into three peaks due to nonzero molecular motion of the anisotropic system. The dependence of quadrupolar splitting on temperature and extent of hydration (controlled by

relative humidity) for ^{23}Na , ^{133}Cs , and ^7Li has been studied in order to elucidate changes in the counterion distributions and binding of Na^+ , Cs^+ , and Li^+ with Na-DNA. Using the temperature dependence of the quadrupolar splitting at different relative humidities, the authors found that a three site model (consisting of free ions and specifically and nonspecifically 'bound' ions) was more consistent with their data than a two site model. In the context of the three site model, Li^+ binds less specifically to DNA than does Na^+ or Cs^+ . For both Na-DNA and Li-DNA, the quadrupolar splitting increases with decreasing concentration of salt (Na^+ or Li^+).

4 ADDITIONAL METHODS OF STUDYING CATION-DNA INTERACTIONS

The focus of this review has been on the applications of quadrupolar NMR relaxation measurements to investigate cation-DNA interactions in dilute solutions, where motional narrowing governs the form of the quadrupolar relaxation processes, and in concentrated solutions. The dilute solution studies represent the earliest, and the largest, body of work in this general field. The concentrated solution studies represent a rapidly growing area, which may be of direct relevance to cation-nucleic acid interactions *in vivo*.

Several other kinds of NMR spectroscopic measurements have also been utilized in studies of cation-DNA interactions. Pulsed field gradient spin diffusion methods have been used to measure the translational diffusion of cations in cation-DNA systems.^{63,64} Applications of these methods will continue to increase as pulsed field gradient technology becomes more readily accessible. The more traditional proton NMR methods are finding increasing popularity as a means of characterizing cation-DNA interactions. For example, the structural effects of cation type and/or concentration on the ^1H spectroscopic characteristics of specific sequence oligonucleotides have been determined in order to correlate changes in ^1H chemical shifts and coupling constants with the B to A transition of a GC-rich octamer induced by $^{59}\text{Co}(\text{NH}_3)_6^{3+}$.⁶⁵ Spectroscopic measurements on ^1H , ^{13}C , and ^{31}P have been used in a similar study to investigate the specific interaction of Zn^{2+} with the N-7 position on guanine nucleotides in the self-complementary oligonucleotide d(ATGGGTACCCAT).⁶⁶

In addition to NMR, thermodynamic and spectroscopic methods have been used to characterize the interactions of cations with DNA. Thermodynamic data have been obtained from Donnan equilibrium and solvent activity measurements, which yield, respectively, preferential interaction coefficients⁶⁷⁻⁷⁰ and osmotic coefficients⁷¹ characterizing the thermodynamic consequences of electrolyte-polyelectrolyte interactions. Calorimetry and ultraviolet spectrophotometry have been applied to investigate the effect of salt concentration on the thermal stability of DNA; these data have been interpreted in terms of the difference between preferential interactions of electrolyte ions with native and denatured states.⁷² Methods other than NMR that have been used to obtain detailed molecular information regarding aspects of the cation radial distribution include small angle neutron scattering⁷³ and fluorescence.⁷⁴

1 INTRODUCTION

Initial analysis of drug complexes with double-helical DNA molecules by hydrodynamic methods indicated that there are two primary binding modes by which drugs interact noncovalently with nucleic acid duplexes: intercalation and minor-groove complexes.^{1,2} Groove-binding molecules can slide into the concave structure represented by the groove, and the compounds typically cause relatively minor structural changes in the double helix. For intercalation to occur, however, a pair of adjacent base pairs must move apart to create a space that is filled by an aromatic system of the intercalator. Because of these structural changes, intercalators cause an increase in the viscosity of linear DNA solutions and an unwinding of closed-circular supercoiled DNA when they bind to the double helix, whereas groove-binding molecules do not cause unwinding of superhelical DNA or increases in the viscosity of linear DNA solutions.¹ It should be noted that intercalators can have substituents with significant interactions in the DNA major and/or minor grooves.

Although the initial studies described above clearly defined the binding modes for a large number of drugs, they provided very limited specific information about the structure of drug–nucleic acid complexes. It was clear with the development of commercial Fourier transform NMR instruments in the early 1970s that NMR could provide valuable new information on intercalation and groove complexes, but the difficulty was to obtain nucleic acid samples appropriate for NMR analysis. Natural DNA under native conditions exists as a double-stranded helix of high molecular weight and limited internal motion. NMR spectra of this molecule and its complexes in solution are too broad to provide useful information.³ Natural RNA, even though single stranded, exists under physiological conditions as highly structured species with extensive sections of intramolecular duplex, and generally gives complex NMR spectra with overlapping signals that are difficult to interpret.⁴ Two initial techniques were developed to obtain NMR information on nucleic acids and their drug complexes: (1) use of synthetic dinucleotides that could potentially form minihelical intercalation complexes, and (2) use of sonicated natural DNA or synthetic polymers to obtain lower molecular

weight duplexes that could bind both intercalators and groove-binding drugs and still give experimentally useful linewidths in NMR spectra.⁵

The studies with dinucleotides were initiated by Chan and co-workers⁶ as part of their research on the interaction of the intercalator ethidium bromide (Figure 1) with single-stranded nucleic acids. These were followed by a very thorough series of NMR studies by Krugh and co-workers⁷ on dinucleotides that could form miniduplexes with intercalators. The work with sonicated DNA provided sequences that were long enough to form complexes with groove-binding drugs as well as intercalators. The hydrodynamic studies described above had been able to group compounds as intercalators or groove binders, but the NMR results showed that more complex, sequence-dependent, binding behavior can occur.⁵

NMR studies showed that classical intercalators, such as ethidium bromide (see Section 2), which contain fused aromatic ring systems, fill the cavity created when two base pairs separate by a distance of 0.34 nm.^{5,7} Groove-binding agents, such as netropsin (see Section 3), contain a series of small, unfused aromatic systems that have torsional mobility to match the twist of the DNA minor groove.^{1,2} Both types of compounds are organic cations that typically have heterocyclic aromatic systems as part of their structure. The effects of nucleic acids on the chemical shifts of intercalators and groove-binding agents are strikingly different.⁵ Nuclei in intercalators experience significant upfield shifts on complex formation primarily due to the shielding effects generated by the aromatic ring currents of the stacked base pairs in duplex structures. The effects on nuclei in the grooves of the double helix are smaller and can be either shielding or deshielding, depending on the location with respect to the base pair edges and other factors that influence chemical shifts.

The development of economical techniques and instruments for the large-scale preparation and purification of nucleic acid oligomers in the late 1970s provided the next major step in the analysis of nucleic acid–drug complexes. Oligonucleotides from the hexamer to dodecamer size were found to form specific double-helical structures with linewidths that were sufficiently narrow to allow high-resolution structural analysis by NMR methods. An explosion of information on the structural and dynamic properties of nucleic acids and their complexes has resulted from the continued developments in NMR and oligomer preparation technologies.

Two major problems can arise in quantitative NMR analysis of nucleic acid–drug complexes. Many of the drugs of interest are organic cations with significant hydrophobic character. These features can give strong complexes with nucleic acids, but they can also cause precipitation and aggregation. A second major problem is the potential for the drugs to form more than one complex with a nucleic acid sequence. This can lead to very complex spectra and/or averaging of NMR results for the different species, depending on the exchange rates among the bound species.⁵ At some exchange rates there can also be a significant decrease in the NOE intensities used for quantitative structural analysis of the complexes. Some of these problems are prevented in the study of covalent complexes. The difficulties with dynamics in the analysis of drug–nucleic acid complexes also exist in the study of these complexes by all solution methods, whether they are recognized or not. Even in the presence of multiple binding modes with dynamics, however, NMR methods can still

provide qualitative information on complexes that in many cases can be combined with molecular modeling methods to define a limiting set of structures for the complex.

NMR results for drug–nucleic acid complexes to be presented will be grouped into categories for noncovalent intercalation and groove-binding agents with a separate category for covalent adducts. One feature of nucleic acid–drug complexes that was not anticipated from other solution or X-ray studies was the binding of drugs to nucleic acids as dimers. Such dimer complexes have been observed by NMR methods for the intercalator actinomycin,^{8,9} for the AT-specific minor-groove agent distamycin,^{10,11} and for the GC-specific minor-groove agent chromomycin.^{12–14} Such dimer complexes provide significant information about cooperativity in nucleic acid interactions, and have provided new ideas for drug design.

2 REVERSIBLE DNA COMPLEXES: INTERCALATORS

There are 10 dinucleotide intercalation sites in antiparallel RNA and DNA duplexes.^{1,2} To create an intercalation site, torsional angle changes occur in the backbone chain to separate the stacked base pairs and unwind the helix, and these changes typically cause downfield shifts in ³¹P NMR spectra.¹⁵ The ring current effects of the base pairs are typically smaller than for the intercalated ring, and most base pair aromatic and imino proton signals at the intercalation site shift to low frequency (upfield) on formation of an intercalation complex. The aromatic proton signals of the intercalator also typically shift to low frequency on transfer from the solvent environment to the base-stacked intercalation complex.⁵ Of the compounds shown to bind to DNA by intercalation, very few have significant binding selectivity for one of the 10 dinucleotide intercalation sites, and the multiple site interactions can complicate NMR studies of their complexes.

Sonicated DNA polymers such as poly[d(G-C)₂] and poly[d(A-T)₂] have single imino proton signals which are shifted upfield by simple intercalators such as ethidium and acridine derivatives.¹⁶ A number of solution studies indicate that binding of simple intercalators saturates at one intercalator per two base pairs, the neighbor exclusion principle. On addition of ethidium to the above polymers, none of the original imino signal remains at saturation, and a single sharp signal for the bound species is obtained; these results indicate that simple intercalators bind at alternating sites on the polymer.¹⁶ If the intercalators clustered into regions on the polymer with other regions relatively free of intercalation, some free GC imino signal would remain, and the bound signal would be more complex.

Oligomers¹⁷ provide higher-resolution NMR spectra, but yield the same basic conclusions as with the polymers. Phosphorus-31 signals for the oligomers fall in the –4.2 to –4.7 ppm range (relative to trimethyl phosphate), and on addition of simple intercalators to saturation move to high frequency in a manner characteristic of intercalation. These results provide strong support for a general intercalation model with the fused intercalation ring system maximally stacked over the DNA base pairs at the binding site. Barton and co-workers¹⁸ have designed a number of metallo-intercalators, and have conducted NMR studies on Δ-Rh(phen)₂phi³⁺

Figure 1 Structures of some intercalators that have been investigated by NMR methods

(phen = phenanthroline; phi = phenanthrene quinone diimide) with the duplex sequence d(GTCGAC). Chemical shift and NOE results indicate that the phi system intercalates with some preference at the C-G step with the phenanthroline rings in the DNA major groove. These and other biophysical studies have resulted in a proposal that such metallo-intercalators can be used to distinguish nucleic acid conformations through a combination of intercalation and nucleic acid shape-specific recognition by the metal ligands in the nucleic acid grooves.¹⁸

Significant intercalation specificity has been observed in studies of DNA complexes of some cationic porphyrins which have a variety of biological activities^{19,20} (Figure 1). Addition of TMpyP(4) to sonicated poly[d(G-C)₂]²⁰ resulted in a high-frequency ³¹P signal at −0.9 ppm relative to the normal polymer ³¹P signal at −4.2 ppm. The high-frequency signal clearly identifies the binding mode as intercalation, and is the largest shift observed for an intercalator complex. TMpyP(4) complexes with oligomers containing 5'-CG-3' intercalation sites have the characteristic porphyrin ³¹P NMR downfield peak at ~−1.0 ppm; however, complexes with oligomers containing either 5'-GC-3' or 5'-GG-3' sites but no CG do not have the high frequency signal.²⁰ Addition of TMpyP(4) to the GC polymer oligomers with CG sites resulted in the appearance of new low-frequency peaks in the imino proton spectra, while oligomers without CG sites did not give the low-frequency imino signals. Surprisingly large imino proton shifts were obtained for protons adjacent to the bases at the CG-binding site. For imino protons that lie at different distances above the porphyrin ring, as expected for an intercalation complex, the imino protons would be at approximately 0.34, 0.68, and 1.02 nm above the porphyrin center for each base pair step away from the bound compound. From these distances, low-frequency shifts of ~4, ~1.2, and ~0.4 ppm, respectively, are predicted for the imino signals from the ring current–chemical shift map for tetraphenylporphyrin,²¹ and the observed shifts are in agreement with the predicted values. In porphyrin–oligomer complexes, very complicated sets of overlapping signals, with different exchange kinetics, are observed in the nonexchangeable proton NMR spectral region, and this system illustrates some of the problems that can arise to prevent detailed structural studies of DNA complexes by NMR methods.

Actinomycin D (ActD), a peptide intercalator (Figure 1) with anticancer and antibiotic activities, is unusual in that it is a neutral molecule which binds strongly to DNA with GC base pair specificity.¹ ActD is generally more well behaved in NMR experiments than the intercalators discussed above, and it was one of the first molecules studied in NMR experiments with dinucleotides and oligonucleotides.⁷ To obtain more detailed information on cooperativity in drug–DNA interactions, ActD complexes with oligonucleotides that contain multiple GC sites have been examined by NMR spectroscopy.^{8,9}

Titration of d(ATGCGCAT) with ActD to a ratio of one ActD molecule per duplex results in a complex imino proton spectrum that no longer has two-fold symmetry. The benzenoid side of the phenoxazine ring of ActD (Figure 1) has a significantly larger ring current than the quinoid side,²² and the observed sets of signals can be explained by the two possible orientations of bound ActD in slow exchange. Increasing the ratio of ActD/duplex to 2:1 results in the disappearance of the 1:1 imino signals, and a significant simplification of the spectrum. At the ratio of 2.0, single signals are seen

Figure 2 A portion of the NOESY spectrum (250 ms mixing time) of the 2:1 ActD complex with the duplex from d(ATGCGCAT). Connectivities within each peptide chain are shown along with the guanine H-1' to Thr- γ cross peak

for the phosphate groups at the intercalation site, and they are shifted significantly downfield.^{8,9} The nonexchangeable proton spectrum of the 1:1 ActD complex is also quite complex; however, the spectrum of the 2:1 complex shows a spectral simplification and return to C_2 symmetry, as with the imino and ³¹P spectra.²³

COSY and NOESY (Figure 2) 2D NMR spectra have provided information for assignment of most proton signals, and for a model of ActD in the dimer complex.⁹ A guanine H-8 resonance at 7.51 ppm and a cytosine H-6 resonance at 7.15 ppm both have NOEs to the ActD H-8 and H-7 signals, showing them to be close to the benzenoid side of the phenoxazine ring of ActD and to be adjacent bases. By a process of elimination, the other guanine H-8 resonance at 7.57 ppm and the cytosine H-6 resonance at 6.59 ppm are close to the quinoid side of the phenoxazine ring and adjacent to each other. A NOE from the thymine H-6 resonance at 6.91 ppm assigns this resonance to the 5'-ATGC end of the oligomer since only the G₃ H-8 of the two guanine residues present can have a NOE to a thymine H-6 signal. Since the guanine H-8 signal at 7.57 ppm is quinoid-G₃, the following order is established: 5'-d(A₁T₂G₃-quinoid-C₄G₅-benzenoid-C₆A₇T₈)-3'. Assignments of the ActD peptide proton resonances and peptide–DNA cross peaks provide the critical information for orientation of the two ActD molecules in the 2:1 complex (Figure 2).

In the 2:1 complex of ActD with d(ATGCGCAT) at least one type of proton in each amino acid could be identified as

belonging to either the benzenoid or quinoid peptides, and, therefore, the two cyclic peptide chains in the 2:1 complex must be in different conformations (Figure 2). Thus, both the oligomer and the antibiotic undergo conformational changes to form the tightly packed 2:1 complex. There is good stacking of the ActD phenoxazine ring with the GC base pairs at the 5'-GC-3' intercalation site, and the amide NH and CO on both peptides of ActD at each GC site are positioned to form hydrogen bonds with the guanine N-3 and amino groups in the minor groove to account for the binding specificity of the intercalator. The N-CH₃ group of *N*-methylVal points into the helix and makes close contact with the A₇ H-2, to give strong NOE cross peaks. Binding of the two ActD molecules in close proximity on the double helix could not be predicted from other studies of ActD complexes, and suggests that drugs of very high specificity and binding strength could be prepared by covalent linking of two ActD molecules.

A shift from the C-2' *endo* to C-3' *endo* sugar conformation, as a result of ActD binding, is suggested by NOESY and COSY results for T₂, C₄, and C₆. These sugar conformational changes can cause a substantial widening of the minor groove, and provide a possible answer to the question of how the four large peptide rings of the ActD 2:1 complex can fit into the narrow minor groove of B-form DNA. Such drug-induced conformational changes demonstrate the inherent flexibility of DNA and its ability to respond to ligand interactions. This type of conformational change may be a common feature of binding of compounds with bulky groups that must fit into the minor groove. Previous ideas, based on the dimensions of the DNA grooves from the B-form structure, concerning the size of the molecules that could fit the major or minor groove, must be reconsidered.

Simple intercalators and even the more complex ActD bind to intercalation sites with the long axis of their aromatic systems approximately parallel to the long axes of the base pairs at the intercalation site. X-ray and other studies of a number of anthracycline drugs, however, indicate that these compounds bind in a bayonet fashion, with their long axis approximately perpendicular to the long axes of the base pairs.^{24,25} Nogalamycin (Figure 1) is an example of naturally occurring anthracyclines which have significant antibiotic and antitumor activity, and its DNA complexes have been extensively studied by NMR methods.

Searle et al.²⁶ obtained 2D NMR spectra on the 2:1 complex formed between nogalamycin and the oligomer d(GCATGC), while Zhang and Patel²⁷ obtained spectra for the complex with d(AGCATGCT). Nogalamycin intercalates at each of the two CA/TG steps and, although three possible complexes are possible, only a single symmetrical complex is observed. The NMR results support a threading intercalation mode with the two sugar moieties residing in opposite grooves—the bicyclic amino sugar occupying the major groove and the nogalose lying in the minor groove. The conformation with sugar residues in opposite grooves is also consistent with the slow association and dissociation kinetics, in that the base pairs at the binding site must temporarily open to allow one of the bulky sugars to slide through during the intercalation reaction. NOE results indicate that the amino and nogalose sugars are directed towards the ends of the duplex. Molecular dynamics calculations constrained by NOE distances were used by Zhang and Patel²⁷ to generate a structure for the complex. In the energy-minimized conformation the bicyclic amino sugar is in

close proximity to the floor of the major groove with its two hydroxyl groups positioned to form hydrogen bonds with N-7 and O-6 of G₆. Additional hydrogen bonding between the nogalose and the G₂ and G₆ amino groups in the minor groove is predicted by the model.

Wang and co-workers examined the 2:1 complex formed between nogalamycin and the hexamer d(CGTACG)₂ by NMR and related hexamers by X-ray crystallography.^{25,28} They found that the nogalose and bicyclic amino sugars are in the minor and major grooves, respectively, with the intercalation site characterized by a wedge shape with significant buckling of the base pairs. Nogalamycin intercalates at the two terminal CG sites in the d(CGTACG)₂ hexamer with the nogalose and bicyclic amino sugars directed toward the center of the oligomer.²⁵ This is in contrast to earlier studies^{26,27} which found the nogalose and bicyclic amino sugars directed toward the ends of the oligomer. To investigate the molecular basis for these differences, Patel and co-workers²⁹ conducted NMR studies on duplexes, d(G₁C₂G₃T₄)·d(A₅C₆G₇C₈) and d(GCAT)·d(ATGC). The latter oligomer forms complexes similar to those observed earlier by Zhang and Patel,²⁷ whereas the d(GCGT) duplex binds nogalamycin in two different complexes of almost equal amounts. In both complexes, nogalamycin is intercalated at the CG sequence with the bicyclic and nogalose sugars in the major and minor grooves, respectively, as in the previous complexes. In one complex the intercalated ring is stacked on the C₆-G₇ bases with the sugars directed at the G₁·C₈ terminus, while in the other complex the ring is stacked with the C₂-G₃ bases with the sugars pointed to the T₄·A₅ terminus.²⁹ The first complex is similar to that observed by Zhang and Patel,²⁷ whereas the second complex is more similar to that observed by Wang and co-workers.²⁸ All of the results are consistent if a nogalamycin has binding specificity for the 3' side of C.²⁹ In this model, nogalamycin binds at the 3' side of a cytosine residue and wraps around the G-C base pair. Formation of specific hydrogen bonds can establish the observed specificity and orientation of the drug.²⁹

Intercalation of compounds containing two or more intercalating rings with DNA has been of interest due to their enhanced potential as anticancer drugs.^{1,2} An initial idea in the development of bis-intercalators was that the antitumor activity of intercalating drugs could be correlated with their DNA binding affinity and dissociation rate, and these features could be enhanced by incorporating more than one intercalator into the same molecular system. The anticancer bis-intercalator ditercalinium (Figure 3) has been extensively investigated with NMR methods by Rogues and co-workers.³⁰ Bis-intercalation with d(CGCG) is confirmed by ¹H NMR and ³¹P NMR, and the neighbor exclusion effect is evidenced by the observed NOE cross peak between the G₂ H-1' and the C₃ H-6, and the lack of connectivities from C₁ to G₂ and from C₃ to G₄ in the d(CGCG) complex. NOEs between ditercalinium aromatic protons and the DNA base protons provide clear evidence for orientation of the aromatic groups of ditercalinium, and require location of the linker chain of the bis-intercalator in the DNA major groove.

Zimmerman and co-workers³¹ have prepared a series of macrocyclic bisacridines (SDM in Figure 3) to determine if such compounds can bind to DNA. NOESY and COSY spectra of the SDM complex with the tetramer d(CGCG) show that the aromatic proton resonances of SDM are shifted upfield upon complex conformation, and that the chemical shift differences

Figure 3 Structures of some natural and synthetic bis-intercalators that have been investigated by NMR methods

between the free and bound states are relatively uniform for all aromatic signals.³² The strongest intermolecular NOE cross peaks are observed between the SDM 2, 3, and 6 resonances and C₁ 2'/2'' resonances, with less intense cross peaks from SDM 3 to C₃ 1' and SDM 2 to G₂ 2''. Significant SDM intramolecular cross peaks are seen between the bisamide side chain and acridines. The NMR evidence is most consistent with a model in which the side chains are in opposite grooves and the acridine rings are both fully intercalated with their long axes approximately parallel to the long axes of the base pairs. Observed cross peaks between the SDM 3 and C₃ 1' NOE protons support a model in which the spermine and bisamide side chains are in the major and minor grooves, respectively. Three pieces of evidence—the lack of full extension for the bisamide linker, the apparent SDM 2 to G₂ 2'' cross peak, and the apparent SDM-binding site size of three base pairs—all suggest a model in which SDM bis-intercalates in violation of the neighbor exclusion principle.³² As with ditercalinium, SDM results illustrate the important structural information that can be obtained on complex and nonideal systems by 2D NMR methods.

Very high DNA sequence recognition is found with bis-intercalators of the quinoxaline antitumor, antibiotic family such as TANDEM (Figure 3). Echinomycin is specific for NCGN sequences while TANDEM binds to sequences centered around TA.^{13,33,34} These compounds give well-behaved DNA complexes, and NMR analyses of their complexes with short oligomers have been conducted by Feigon,³³ Patel,³⁴ and

their co-workers. Results for CysMeTANDEM (Figure 3) complexes with the self-complementary duplex, d(GATATC), are typical of this group and illustrate their sequence recognition mechanism.³³ Distance and angle constraints for the complex were derived from NOESY and COSY data sets, while initial structures were obtained from distance geometry, and were refined with the NMR-derived constraints. The two aromatic rings bis-intercalate at the AT sequence steps, and the cyclic peptide is in the minor groove at the TA sequence. Specific hydrogen bonds between the Ala NH and adenine N-3 groups at the TA step along with specific van der Waals interactions account for much of the AT specificity of TANDEM derivatives.³³ Similar interactions at CG sequences account for the specificity of echinomycin-type bis-intercalators, although complex peptide and groove interactions, which are still not completely understood, are apparently required for the high observed level of specificity.^{13,33,34} NMR results for these peptide-linked bis-intercalators provide a striking example of DNA sequence recognition differences that occurs as a result of relatively small changes in the peptide systems.

3 REVERSIBLE DNA COMPLEXES: MINOR-GROOVE INTERACTIONS

There are a number of antibiotics and synthetic drugs (Figure 4) that have been shown to bind with base pair

Figure 4 Structures of some natural and synthetic minor-groove binding drugs that have been investigated by NMR methods

specificity in the minor groove of DNA.^{1,2} Compounds such as netropsin form hydrogen bonds with groups on the floor of the minor groove, and the 0.34 nm thickness of the conjugated system of the drugs allows formation of good van der Waals contacts with the walls of the narrow minor groove in AT-rich sequences.^{1,2} The amino group of guanine generally prevents such molecules from sliding deeply into the minor groove at GC sites, and the minor groove is generally wider with a less negative electronic potential in sequences with GC base pairs. Wemmer, Dervan, and co-workers^{10,11,35} have shown, however, that dimers of distamycin and analogs can bind in the minor groove of GC-containing DNA sequences. Chromomycin binds exclusively in the minor groove at GC sites as a magnesium ion-linked dimer.^{12–14} DAPI (Figure 4)

has extremely interesting sequence-dependent interactions with DNA.^{36–38} NMR and other biophysical studies indicate that DAPI binds strongly in the minor groove in AT sequences, but intercalates in GC sequences. The compounds in Figure 4, thus, have very different interactions with DNA, and an analysis of NMR results for some of their complexes is presented here.

Pelton and Wemmer¹⁰ used NMR distance constraints in molecular mechanics calculations for distamycin–d(CGCGA ATTGCG), and derived a structure with distamycin in the minor groove at AATT. The amidinium group is in the center of the groove, and there are several hydrogen bonds, generally somewhat long, between the amidine N–H and the adenine N-3 and thymine O-2 atoms at the floor of the minor groove. A very interesting stacking of deoxyribose O-1' atoms over each of

the three pyrrole rings of distamycin, which may be a common feature in nucleic acid groove complexes, was observed.

Analyses of distamycin complexes with oligomers that have longer AT sequences were surprising.¹¹ With the sequence d(CGCAAATTGGC) and its complementary chain (referred to as A₃T₂), NMR evidence suggested that four possible single distamycin-binding sites, each with four consecutive AT base pairs, were populated at low ratios of distamycin. As the ratio was increased, however, a new set of peaks appeared and, at a 2:1 ratio, these new peaks were the only ones present. These observations, and the fact that two sets of distamycin NMR signals are present, indicated that two distamycin molecules bind in different orientations at the 2:1 ratio. Intermolecular NOESY peaks indicate that the bound drugs are oriented in opposite directions, with their positive charges pointing to the ends of the duplex. In the 2:1 model the binding of two adjacent distamycins in the AT-rich minor groove must cause a significant widening of the groove to accommodate the two bound drugs.¹¹ Since the minor groove in AT sequences is normally quite narrow, this involves a significant conformational change.

Wemmer, Dervan, and co-workers have extended the dimer analysis by preparation and NMR analysis of a methylene bridge-linked series of distamycin analogs (Figure 4).³⁵ Binding of the dimers and monomer unit were investigated by NMR titrations with the DNA sequence d(GCATGACTCGG) and its complementary strand. The monomer bound as a cooperative dimer in the 5'-TGACT-3' site to give a unique peptide-DNA complex. The covalent dimers all formed 1:1 complexes with the same site, suggesting that very similar complexes were formed with the cooperative and covalent dimers. The linker length had little effect on the complexes with this system. 2D NMR studies indicated that both the 2:1 monomer and 1:1 dimer complexes bound in an antiparallel manner, with the aromatic rings of one ligand overlapping the amide bonds of the other unit, as observed for the distamycin dimer.³⁵ In all complexes one peptide unit spans the TGAC sequence while the other contacts the AGTC sequence on the opposite strand. Such an orientation allows the two pyridine systems of the dimer to form hydrogen bonds with the 2-amino groups of the guanine residues at the floor of the minor groove, and can account for the sequence recognition for these linked systems. NMR studies played the key role in the discovery and characterization of these dimer systems, which present exciting new possibilities for drug development.^{10, 11, 35}

Chromomycin (CRA, Figure 4) belongs to the aureolic acid group of antitumor antibiotics that exert their biological effects through complex formation with DNA.¹ All compounds of this group have pronounced GC base pair binding specificity, and require a divalent cation such as Mg²⁺ for strong DNA binding. Gao and Patel^{12, 13} observed complex ³¹P chemical shift changes on addition of CRA to the sequence d(T₁T₂G₃G₄C₅C₆A₇A₈): signals for the T₂-G₃ and G₃-G₄ phosphate groups moved to high frequency, and signals for the G₄-C₅, C₆-A₇, and C₅-C₆ phosphates moved significantly to low frequency in the CRA complex. These results are highly suggestive of groove binding, and they demonstrate that CRA-DNA interactions are unusually complex. A single new signal for each imino proton is observed from low ratios of CRA to 2:1 CRA/oligomer, and at a 1:1 ratio bound and free signal areas are approximately equal. These results indicate that two CRA molecules bind per oligomer in a

unique 1 Mg²⁺:2CRA:1 duplex complex that maintains the C₂ symmetry present in self-complementary oligomers.¹²⁻¹⁴

2D NMR results establish both the minor-groove binding mode of CRA and the orientation of the CRA sugar rings in the bound dimer.¹²⁻¹⁴ The E-sugar of CRA (Figure 4), for example, has several NOE cross peaks with the A₇ protons in the sequence d(TTGGCCAA), indicating that the E-sugar makes close contact with the 3' end of the strands of the duplex. The chromophore methyl group protons have a weak NOE with the G₃ amino protons in the sequence, and this contact orients the hydrophilic face of the CRA aromatic systems into the minor groove in the bound dimer. Spectral changes in some deoxyribose residues that are characteristic of a shift from the C-2' to a C-3' *endo*-type conformation suggest that a transition to a more A-like conformation, with a wider and more shallow minor groove is occurring in the complex. Gao and Patel^{12, 13} found that the dimer of CRA could be docked into a sterically acceptable complex with an A-form DNA conformation, and that such a complex satisfied the proton-proton distances predicted from the NOE results. Hydrogen bonds from the CRA phenolic group to guanine stabilize the complex, and could account for the GC binding specificity of CRA. The DNA sequence recognition motif of CRA is, thus, quite different from that of the AT-specific minor-groove agents which bind in the narrow minor groove in B-form DNA at AT-rich sequences.

DAPI and berenil (Figure 4) are aromatic diamidines with the charges, molecular shape, and array of N-H hydrogen bond donating groups on one face of the molecule that are characteristic of AT-specific, minor-groove interactions.^{1, 2} NMR results with DAPI-poly[d(A-T)₂]³⁶ and berenil-d(CGC GAATTCGCG)³⁹ complexes are similar to those obtained with netropsin, and support an AT-specific, minor-groove interaction for the diamidines. The size and planarity of the aromatic system of DAPI, however, suggested that in GC sequences, where minor-groove binding is inhibited, DAPI could bind by intercalation.³⁶⁻³⁸ This concept of sequence-dependent binding modes is difficult to detect with most biophysical techniques, but it was confirmed with comparative NMR studies of DAPI-DNA complexes. Addition of poly[d(G-C)₂] causes dramatic upfield shifts of the DAPI aromatic protons, as expected for intercalation.³⁷ The relative shifts of the protons on the indole ring are particularly informative (Figure 5). In the GC complex the H-3 and H-4 atoms, near the center of the molecule, shift significantly farther to low frequency than H-5, which is at the edge of the molecular long axes. This is exactly the shift pattern expected for intercalation of the DAPI molecule with its long axis approximately parallel to the long axes of the base pairs at the intercalation site. The protons H-3, H-4, and H-5 all shift slightly to high frequency in the complex with poly[d(A-T)₂].³⁶ The high-frequency shift of H-7 in the AT complex is larger than for the other protons of DAPI, and this finding agrees with the proposed minor-groove binding model for DAPI with the indole H-7 and the NH group facing into the edges of the AT base pairs in the minor groove. The deshielding effects of the base pair ring currents are maximized at their edges and H-7, thus, experiences the largest deshielding shift in the AT-DAPI complex.³⁶

Figure 5 A schematic of the observed proton NMR chemical shift changes that occur when DAPI binds to (a) GC and to (b) AT sites in DNA

Other NMR results also support the sequence-dependent binding modes of DAPI. The imino proton on poly[d(A-T)₂] becomes deshielded and the imino proton of poly[d(G-C)₂] shielded on the addition of DAPI. The ³¹P signals of the AT polymer shift to low frequency, and those of the GC polymer to high frequency, as expected, respectively, for groove and intercalation binding modes. The inescapable conclusion is that DAPI binds by intercalation at GC and mixed AT/GC sites, and in a minor-groove complex at AT sequences. Recent NMR studies with RNA complexes of DAPI provide information about the influence of helix type on binding mode. In RNA sequences containing only AU base pairs, NMR studies indicate that DAPI binds by intercalation, not by complex formation in the minor groove as with AT sequences in DNA.³⁸ Since the minor groove conformations of A-form RNA and B-form DNA are very different, but intercalation sites in DNA and RNA can be quite similar, intercalation of DAPI with RNA AU sequences fits quite well with current knowledge of nucleic acid conformation and its influence on binding mode.³⁸ NMR studies have been essential in establishing the sequence and helix-type dependence of the DAPI-binding mode, and show that the binding mode with the lowest free energy is determined by factors such as the nucleic acid sequence and conformation as well as by the shape and substituents of the ligand.

4 COVALENT DNA COMPLEXES

A number of covalent drug–DNA adducts have been investigated with NMR methods. Covalent adducts have been found as intercalated as well as both major- and minor-groove species. The major-groove complexes are best represented by the widely used anticancer metallo-drug *cis*-Pt(NH₃)₂Cl₂ (*cis*-diamminedichloroplatinum, *cis*-DDP) and related derivatives. Marzilli and co-workers^{40,41} have shown with NMR that the reaction of *cis*-DDP with DNA can cause dramatic structural changes in the duplex. Hurley and co-workers have conducted

Figure 6 Structures of some anticancer drugs that bind covalently to DNA and have been investigated by NMR methods. A portion of the covalent adduct of CC-1065 with N-3 of A is also shown

detailed NMR studies of covalent organic compounds that react in the minor groove at guanine residues, such as anthramycin,⁴² or at adenine residues, such as CC-1065,⁴³ or which intercalate, such as altramycin B⁴⁴ (Figure 6).

The adducts formed between *cis*-DDP and N-7 of guanine are the principal products formed on reaction with DNA, the likely *in vivo* target of the drug.^{40,41} A major product involves reaction at intrastrand adjacent guanine N-7 atoms, and this adduct can cause severe distortion of the DNA duplex. The difficulty with NMR studies of such distorted DNA complexes is that key NOE cross peaks can be lost, and standard sequential ¹H assignment procedures may not be possible. In such cases, ¹³C NMR methods can provide useful assistance for ¹H assignments, and can give valuable structural information. The model system d(T₁G₂G₃T₄)–Pt(en), where en = ethylenediamine, which has N-7 of both guanines reacted with platinum, has been studied by a variety of NMR methods.⁴¹ Heteronuclear scalar connectivities assisted in the assignment of the complex, and ¹³C NMR chemical shift changes were used to identify the platinum cross-linking sites. The C-3' signal of G₂ was shielded by 6.6 ppm on reaction of the tetramer with the platinum drug, and such shifts are characteristic of a sugar conformational change from C-2' *endo*

to C-3' *endo*. The ^{13}C spectrum of the platinum-oligomer does not change significantly with temperature while the spectrum of the free oligomer shows significant changes with temperature. These comparisons indicate that the platinum reaction of DNA induces large conformational changes, and that the resulting conformations are quite stable to temperature changes.⁴¹

Results with CC-1065 illustrate a number of interesting features of covalent complexes of organic drugs with DNA, and demonstrate the use of NMR methods to define the molecular basis of sequence selectivity and induced conformational changes in DNA.^{43,45} The drug reacts preferentially at two consensus DNA sequences: 5'-PuNTTA* and 5'-AAAAA* (where A* indicates the modified base, see Figure 6). The reactive cyclopropane ring alkylates N-3 of adenine when CC-1065 binds to the above sequences. NMR studies have shown that in the product the major form of the reacted adenine is as the cationic doubly protonated amino form (Figure 6), and that a water molecule organized in the noncovalent initial complex is part of a catalytic mechanism for the reaction of CC-1065 with DNA.^{43,45} The structured water molecule has been detected by proton NMR analysis of the covalent product in ^{17}O -enriched water. Selective broadening of the phenolic hydrogen in the reactive-A subunit (see Figure 5) in ^{17}O -enriched water suggests that a structured water bridges the phenolic group and a phosphate oxygen on the strand of DNA that is not reacted with CC-1065. A ~ 2 ppm deshielding of the phenolic proton on the A relative to the B and C subunits in the complex supports this model. The ordered water apparently plays a role in activation of CC-1065 for covalent linkage to N-3 of A after the drug binds in the minor groove.⁴⁵

The ^{17}O results also suggest that a structured water is necessary to bridge the amino group of the reacted adenine and its complementary thymine.⁴⁵ Bending of DNA and propeller twist of base pairs near the site of reaction may require the additional water in the major groove to bridge the reacted base pair. Ordered water, as demonstrated by NMR methods with CC-1065, may play a role in other nucleic acid reactions, recognition mechanisms, and structure stabilizations. NMR results have also demonstrated that the bend in the DNA helix induced by reaction with CC-1065 is similar to the natural bend caused by repeating adenine tracts.^{43,45} The results suggest that deformability of DNA sequences may be an additional significant contributor to the sequence selectivity in reaction of CC-1065. Covalent drugs, thus, initially bind to DNA with the same sequence recognition mechanisms as noncovalent drugs, but in their reaction with DNA other factors, such as catalytic activation and sequence deformability, can play a major additional role in refining sequence recognition.^{43,45}

5 OVERVIEW

In the relatively short period of overlap of modern high-field FT NMR and oligomer synthesis capabilities, a wealth of new and, in many cases surprising, results have appeared for drug-nucleic acid complexes. Some of the unexpected and very interesting results that have been presented in this article include: the dimer-binding modes of distamycin, chromomycin and actinomycin; the AT minor-groove and GC intercalation modes for some unfused aromatic cations such as DAPI; a structured water involved in catalysis of the CC-1065 reaction

with N-3 of adenine in the minor groove; and a variety of findings on the molecular basis of binding specificity and complex dynamics. Detailed understanding of these important features of nucleic acid complexes has only been possible through high-resolution NMR studies. As NMR and oligomer synthesis capabilities continue to advance, it is certain that more interesting, unexpected, and important new results for drug-nucleic acid complexes lie in our future.

1 INTRODUCTION

Proton–carbon-13 half-filters divide a ^1H NMR spectrum into two subspectra, where one contains the signals from protons bound to ^{13}C and the other the signals of the protons bound to ^{12}C . Half-filters can be applied quite generally to heteronuclear two-spin systems where both nuclei carry a spin- $\frac{1}{2}$ and are coupled to each other. Apart from ^1H – ^{13}C half-filters, ^1H – ^{15}N half-filters are of the greatest use with biological samples. Originally, half-filters were used in combination with selective labeling of the biomolecules at defined positions with ^{13}C or ^{15}N to obtain a considerably simplified subspectrum of the ^{13}C or ^{15}N ‘labeled’ protons.^{1,2} The name ‘half-filter’ was chosen because any one of these filter elements acts exclusively in one dimension of a 2D NMR experiment without selecting amongst the resonances in the other frequency dimension. This property is also the main difference to the so-called *X* filters, which select the cross peaks between protons coupled to the same heteronuclear spin *X*.³ Further related filters have been developed for special applications that select the protons coupled to more than one heteronuclear spin.⁴ With the availability of more powerful computers and larger disks, uniform ^{13}C and ^{15}N labeling has become increasingly popular, because the development of a ^1H – ^{13}C 2D NMR spectrum into a third and fourth dimension by the heteronuclear chemical shifts often provides sufficient resolution to assign a large number of ^1H – ^1H cross peaks with a single isotope enriched sample. In the context of uniform isotope enrichment, half-filters have a particular interest in studies of protein–ligand complexes, where the protein partner is uniformly enriched with ^{13}C or ^{15}N while the ligand is not.⁵ In this situation, a ^1H – ^{13}C half-filter is able to select the cross peaks with the ^{12}C bound protons of the ligand whereas a higher-dimensional experiment using the ^{13}C chemical shift in an additional dimension would suppress the signals of the ^{12}C bound protons. The combination of two half-filter elements in the experiment results in a so-called double half-filter, which allows the selective observation of the ^1H – ^1H cross peaks between the unlabeled ligand protons in the complex, while the cross peaks with the labeled protein are directed into different subspectra. Clearly, the spectral editing can be

extended further by combining a ^1H – ^{13}C half-filter with a ^1H – ^{15}N half-filter or an *X* filter, and one could in principle also imagine half-filters between two nonproton spins, e.g. ^3H and ^{13}C . In biological applications, the proton spins are of most interest because of their high natural abundance and sensitivity, and because of the structural information contained in ^1H – ^1H NOEs. In the following discussion, ^1H – ^{13}C and ^1H – ^{15}N half-filters will be referred to as ^{13}C half-filters and ^{15}N half-filters, respectively. The present article uses ^{13}C half-filters as examples to discuss the principles of half-filters and presents illustrative applications.

2 HALF-FILTER ELEMENTS

There are two different half-filter elements which can be used in a pulse sequence. The half-filter element of Figure 1(a) refocuses the one-bond $^1J(^{13}\text{C}, ^1\text{H})$ coupling so that ^{13}C broadband decoupling can be used throughout the rest of the pulse sequence. The half-filter element of Figure 1(b) is shorter, but results in heteronuclear antiphase magnetization which precludes heteronuclear decoupling unless the filter is used only to select for ^{12}C bound protons. The delay τ is set to $1/[2^1J(^{13}\text{C}, ^1\text{H})]$. Two data sets are recorded which differ only by the phase ϕ of the editing $90(^{13}\text{C})$ pulse (Figure 1).

The functioning of a half-filter is most easily understood in terms of a product operator description⁶ for the spins of an isolated ^1H – ^{13}C group and of a ^1H – ^{12}C group. Because of the $180(^1\text{H})$ pulse in the center of the filter elements, the chemical shift evolution of the protons is refocused so that only the evolution under the heteronuclear coupling needs to be considered. Starting from in-phase proton magnetization along the *x* axis, H_x , the heteronuclear coupling leads to antiphase magnetization, $2\text{H}_y\text{C}_z$, at the end of the delay τ for the ^1H – ^{13}C group. The following two $90(^{13}\text{C})$ pulses are either of the same or the opposite phase, resulting in, respectively, an effective $180(^{13}\text{C})$ pulse which inverts the sign of the magnetization $2\text{H}_y\text{C}_z$, or a $0(^{13}\text{C})$ rotation which has no further effect on the magnetization. The magnetization of the ^{12}C bound proton is in no instance affected by the pulses applied at the ^{13}C frequency. Therefore, subtraction of the data recorded with and without the effective $180(^{13}\text{C})$ pulse selects the magnetization of the ^1H – ^{13}C group and cancels the response from the ^1H – ^{12}C group, whereas summation of the data selects the proton signal from the ^1H – ^{12}C group and suppresses the signal of the ^1H – ^{13}C group.

Figure 1 Carbon-13 half-filter elements. In this and the following figures, narrow and wider rectangles denote 90° and 180° pulses, respectively. The delay τ is optimally set to $1/[2^1J(^{13}\text{C}, ^1\text{H})]$. In recording an experiment with a half-filter, two data sets are recorded with the phase ϕ of the second $90(^{13}\text{C})$ pulse (the ‘editing pulse’) set to $+x$ for one data set and $-x$ for the other. (a) Half-filter element with refocusing. (b) half-filter element without refocusing

The description of the half-filter technique in terms of isolated H-C groups also holds to a good approximation for the more complicated spin systems encountered in biomolecules, because the one-bond coupling $^1J(^{13}\text{C}, ^1\text{H})$ is much larger than any scalar coupling between protons. Moreover, the one-bond coupling constant is nearly the same for all $^1\text{H}-^{13}\text{C}$ groups, so that the delay τ can be set rather accurately to $1/[2^1J(^{13}\text{C}, ^1\text{H})]$. If $\tau \neq 1/[2^1J(^{13}\text{C}, ^1\text{H})]$, some of the signal intensity from the ^{13}C bound protons will appear in the sum spectrum instead of in the difference spectrum ('crosstalk').⁴ In principle, the half-filter technique neither generates nor suppresses any of the cross peaks present in the unedited experiment. Losses in effective peak intensities have to be expected only from the relaxation during the short filter delay, any spread among the different one-bond $^1\text{H}-^{13}\text{C}$ coupling constants, and pulse imperfections. Loss of signal due to off-resonance effects of the ^{13}C pulses can be reduced by inserting a refocusing $180^\circ(^{13}\text{C})$ pulse between the two $90^\circ(^{13}\text{C})$ pulses of the ^{13}C half-filter.⁷

3 IMPLEMENTATION OF HALF-FILTERS IN PULSE SEQUENCES

Half-filters can be used with any of the evolution periods in a multidimensional NMR experiment or with the detection period. The names $^{13}\text{C}(\omega_1)$ half-filter, $^{13}\text{C}(\omega_2)$ half-filter, etc., can be used to emphasize the fact that the half-filter will be effective only in the respective frequency dimensions. Figure 2(a) and (b) illustrate how the half-filter element of Figure 1(a) can be implemented in a NOESY pulse sequence as a $^{13}\text{C}(\omega_2)$ half-filter and a $^{13}\text{C}(\omega_1)$ half-filter, respectively. This filter element can be used with ^{13}C decoupling, which is achieved by a $180^\circ(^{13}\text{C})$ pulse in the middle of the t_1 evolution period and broadband decoupling during the detection period, or broadband decoupling during both t_1 and t_2 .

Figure 3 shows an example of a NOESY spectrum with a $^{15}\text{N}(\omega_2)$ half-filter recorded with the pulse sequence of Figure 2(b).² The compound is a peptide where the residues Gly10, Ala17, and Gly20 were selectively labeled with ^{15}N . Figure 3(a) shows the conventional NOESY spectrum with heteronuclear broadband decoupling but without a half-filter. The amide proton resonances of the three ^{15}N -labeled residues are around 8 ppm, where they overlap with the signals from other amide protons. The two subspectra obtained with the $^{15}\text{N}(\omega_2)$ half-filter are shown in Figure 3(b) and (c). Figure 3(b) was obtained as the difference between the two data sets recorded with different phases of the editing $90^\circ(^{15}\text{N})$ pulse. It contains exclusively those diagonal and cross peaks which involve the resonances of the three isotope-labeled amide protons in the ω_2 frequency dimension. Figure 3(c) is the sum spectrum which contains all other peaks from the unfiltered NOESY spectrum of Figure 3(a).

Figure 2(c) shows an example of the filter element of Figure 1(b) implemented in a TOCSY pulse sequence. The half-filter has been supplemented by a spin lock pulse which is applied with the same phase as the first $90^\circ(^1\text{H})$ pulse. Its effect is to purge the magnetization of the ^{12}C bound protons and to retain only the magnetization of the ^{13}C bound protons so that only the difference spectrum contains meaningful information. The purpose of the purge pulse is to suppress

Figure 2 2D NMR experiments with ^{13}C half-filters. (a) NOESY with $^{13}\text{C}(\omega_2)$ half-filter. (b) NOESY with $^{13}\text{C}(\omega_1)$ half-filter. (c) TOCSY with the $^{13}\text{C}(\omega_1)$ half-filter element of Figure 1(b) supplemented by a spin lock purge pulse SL of about 1–2 ms duration. The TOCSY mixing sequence during τ_m is denoted by a long bar. For appropriate phase cycles see Otting and Wüthrich⁴

Figure 3 NOESY spectra of the fragment 7–23 from the atrial natriuretic factor in sodium dodecyl sulfate micelles. Nitrogen-15 decoupling in ω_1 and ω_2 was used in all experiments. (a) Conventional NOESY spectrum. (b), (c) Difference and sum spectrum of the NOESY experiment with a $^{15}\text{N}(\omega_2)$ half-filter. The half-filter delay τ was set to 5.38 ms. At the top the amide proton chemical shifts are indicated for selected amino acid residues. The residues G10, A17, and G20 were selectively labeled with ^{15}N . (Reproduced by permission of Academic Press from Fesik et al.²)

the signals from the ^1H - ^{12}C groups sufficiently to obtain an artifact-free subspectrum of the protons bound to ^{13}C at natural abundance. This pulse sequence has been used to observe the cross peaks between ^{13}C bound protons and ^{12}C bound protons in BPTI (bovine pancreatic trypsin inhibitor) (see *Pancreatic Trypsin Inhibitor*) at natural isotope abundance.⁴ Since no pulses are applied at the ^{13}C frequency after the half-filter element [Figure 2(c)], each cross peak has an ECHO-type appearance⁸ with two major multiplet components, where the relative displacements in the ω_1 and ω_2 dimensions represent, respectively, the large $^1J(^{13}\text{C}, ^1\text{H})$ coupling constant, and the long range heteronuclear coupling constants between the protons detected along ω_2 and the ^{13}C spin of the CH groups detected along ω_1 . The technique enables the measurement of heteronuclear coupling constants which are smaller than the linewidth of the signal.⁹

4 DOUBLE HALF-FILTER

Two half-filter elements may be used with different evolution or detection periods in the same experiment, resulting in a double half-filter.⁴ Figure 4(a) shows an example of a NOESY pulse sequence with a $^{13}\text{C}(\omega_1, \omega_2)$ double half-filter. The combination of the $^{13}\text{C}(\omega_1)$ half-filter with the $^{13}\text{C}(\omega_2)$ half-filter leads to the presence of two $90^\circ(^{13}\text{C})$ editing pulses. Each editing pulse is applied either with the same or the opposite phase relative to the phase of the preceding $90^\circ(^{13}\text{C})$ pulse of the respective half-filter element. The four data sets recorded with the four possible combinations of phase settings of the editing pulses can be combined into four different subspectra which select or reject ^{13}C bound protons along ω_1 or ω_2 .

Figure 5 presents as an illustration the four different subspectra of a homeodomain-DNA complex recorded with the pulse sequence of Figure 4(a).^{10,11} The protein was uniformly enriched with ^{13}C , while the DNA was unlabeled. The four different subspectra contain the following NOESY peaks: (a) diagonal peaks and cross peaks between ^{13}C bound protons in ω_1 and ω_2 that correspond to the intramolecular NOEs of the ^{13}C -labeled protein; (b) diagonal peaks and

cross peaks between ^{12}C bound protons in ω_1 and ω_2 that correspond to the intramolecular NOEs between the protons of the DNA; (c) cross peaks between ^{12}C bound protons in ω_1 and ^{12}C bound protons in ω_2 that correspond to intermolecular NOEs between the DNA and the protein; and (d) cross peaks between ^{13}C bound protons in ω_1 and ^{12}C bound protons in ω_2 . The last subspectrum corresponds to the subspectrum of Figure 5(b) with mutually exchanged frequency axes.

Variants of the double half-filter include the use of ^{13}C and ^{15}N half-filters in different dimensions of the same experiment,⁷ or the simultaneous application of ^{13}C and ^{15}N half-filters in a time-shared fashion.¹²

5 HALF-FILTERS AND MULTIDIMENSIONAL NMR

In principle, any experiment containing a ^{13}C half-filter element can be expanded into a new experiment with the chemical shifts of the ^{13}C nuclei in a further dimension. As a drawback, the signals from the ^{12}C bound protons cannot follow the expansion into the new dimension and are usually eliminated by the phase cycling. Half-filters are therefore the most attractive alternative when the signals of ^{12}C bound protons need to be selectively observed without losing the corresponding cross peaks with the ^{13}C bound protons. If the information on the ^{13}C bound protons can be dispensed with, a specifically optimized ^{13}C reject filter may be more efficient in selecting the resonances of the ^{12}C bound protons.¹³⁻¹⁵

It is instructive to compare the different NOESY experiments which would give the maximum resolution for the ^1H - ^1H NOEs in a protein-ligand complex in which the protein is uniformly enriched with ^{13}C and the ligand unlabeled. The 4D HMQC-NOESY-HMQC experiment [Figure 4(c)] would resolve the intramolecular NOEs of the protein by frequency labeling each proton chemical shift with the chemical shift of the directly bonded ^{13}C spin in another dimension.¹⁶ Comparison of the pulse sequences of Figure 4(a) and (c) shows that the sequence of the 4D HMQC-NOESY-HMQC experiment can be derived from the sequence of the 2D NOESY with a $^{13}\text{C}(\omega_1, \omega_2)$ double half-filter simply by insertion of an incrementable evolution period between the two $90^\circ(^{13}\text{C})$ pulses of each of the half-filter elements. Expanding only one of the ^{13}C half-filters into a HMQC element leads to the 3D HMQC-NOESY experiment with a $^{13}\text{C}(\omega_3)$ half-filter of Figure 4(b) or to the equivalent 3D NOESY-HMQC experiment with a $^{13}\text{C}(\omega_1)$ half-filter (sequence not shown). The latter two experiments enable the selective observation of intermolecular NOEs between ^{13}C and ^{12}C bound protons at the resolution of a 3D NMR experiment while at the same time the cross peaks between ^{13}C bound protons are directed into another 3D subspectrum.

Figure 4 Pulse sequences of (a) 2D NOESY with a $^{13}\text{C}(\omega_1, \omega_2)$ double half-filter, (b) 3D HMQC-NOESY with a $^{13}\text{C}(\omega_3)$ half-filter, (c) 4D HMQC-NOESY-HMQC experiment. For appropriate phase cycles see Otting and Wüthrich⁴ and Clore and Gronenborn¹⁶

1 INTRODUCTION

Antibodies form the basis of the body's defence against infection. The central importance of antibodies to biology is expressed in the functional versatility of the antibody molecule and realized through its unique structure (Figure 1). Thus, the organization of the antibody molecule into domains allows recognition of a virtually unlimited range of antigens by the variable part of the structure, whereas the constant part mediates a small number of effector systems related to antigen elimination and/or immobilization. In this article we will confine the discussion to our work on defining the structural basis for the initial recognition of antigens by antibodies. X-ray data have confirmed the idea that antibody combining site involves a cleft or groove constructed from both the heavy and light chain (Figure 1). The amino acids in the site vary for different antibodies, and are thus termed hypervariable.

1.1 Antibody Specificity

One of the central problems in immunochemistry is the structural basis of antibody specificity; how does such a high diversity in molecular recognition reside in what seems to be a family of proteins closely related in their chemical structure? The pioneering X-ray analysis of Fab' fragments of homogenous myeloma proteins led to the elucidation of the three-dimensional structure of the binding site of two antibodies: the human protein New, which bound vitamin K, and the mouse protein McPC 603, which bound phosphorylcholine.^{1,2} From these studies it was clear that the residues forming the sites that are complementary to the antigen are contributed by the hypervariable regions³ (three segments of 5–10 residues each, in both light and heavy chains) and that replacements of amino acid residues in these segments will generate binding sites with new specificities. Such replacement will not disturb the 'immunoglobulin fold' of the variable domains, which remains similar in all antibodies. Thus on a background of a common three-dimensional structure a vast number of specificities can be generated. This diversity in recognition is the essence of the immune system, and therefore a comparative analysis of combining sites is required in order to provide the details of molecular recognition by antibodies. In this respect, it was

also important to develop new methodologies by which the structure of the antibody site could be analyzed in solution and yield information comparable with that obtained from crystal studies.

1.2 NMR Approach to Studying Binding Sites

Our approach to studying combining sites mainly involved using high-resolution NMR together with crystallographic data,^{4–6} and our general scheme is shown in Figure 2. When refined crystal structures are available, the NMR data can usually be interpreted directly on the basis of that structure. The contribution of NMR in such cases is then mainly to measure binding constants and to probe the role of ionizable groups (thermodynamic measurement) to give information on pairwise interactions [which allow the precise positioning of nuclei (< 0.05 nm)] and to give information on motional dynamics of nuclei on individual amino acid residues. Where X-ray structural data are not available, NMR can still be used to give a 'fingerprint' of the site, and while this is useful in comparing different antibody sites, it is essentially a qualitative approach.

1.2.1 The Immunoglobulin Fold

Immunoglobulin molecules possess a unique structural fold—the immunoglobulin fold—which suggests that it is possible to predict structures of combining sites. This would then offer a starting point for the interpretation of NMR studies. This predictive method follows from X-ray work, which has established that the structure of immunoglobulin domains is very similar and that the basis for this similarity is the conservation of a framework structure, i.e. the immunoglobulin fold.^{7–11} Similarity is particularly marked when equivalent domains are compared. Thus, it is possible to predict the structure of an immunoglobulin domain by aligning its amino acid sequence with that of an equivalent domain of a known structure.^{11,12} A binding site can be generated by building the conserved framework (the immunoglobulin fold) and attaching to it the (hypervariable) sequences of amino acids which form the antigen binding site. The resulting model may then be tested against NMR and the physicochemical data, and modified accordingly.⁶ If validated, such a procedure provides an important complementary approach to crystallographic studies and is of particular use for immunoglobulins which cannot be crystallized or for which high resolution X-ray data cannot be collected. When combined with site-directed mutageneses the NMR approach allows the importance of individual amino acid residues in binding to be assessed.

1.2.2 Three Different Types of Binding Sites

The main test case of the spectroscopic and combined model building approach to studying antibody combining sites is clearly the DNP (2,4-dinitrophenyl) binding IgA (immunoglobulin A) myeloma M315, which is probably the myeloma protein most studied by physical techniques and for which preliminary crystal data are now available.^{13,14} There is broad agreement with the NMR model. This suggests that

Figure 1 Basic antibody structure showing the constant (C) and variable domains (V) of the heavy (H) and light (L) chains. In a given class the amino acids in the constant regions do not differ greatly with different specificities in contrast to those on the variable region. Those amino acid residues actually contributing to the site within the (V) regions are termed hypervariable. There are three such regions for each chain (H1, H2, H3 and L1, L2, L3). Immunoglobulin G (IgG)

Figure 2 NMR approaches to antibody binding sites and prediction of hapten sites

the approach outlined here may provide a general method for studying any antibody combining site.

The majority of our work involved studying the resonance of the ligand (or hapten) when bound in the antibody combining site. However, in many cases, the use of the ^1H NMR difference spectra obtained with the addition of the ligand proved surprisingly successful. Such NMR difference spectra have been analyzed and shown to contain resonances from those relatively few nuclei of the amino acids in and near the combining site. This provides an NMR 'subpectrum' of

the antibody site which can be used in comparative studies. For example,¹⁵ Figure 3 shows the poorly resolved aromatic region of the Fab fragments (molecular mass 50 000 Da) of the sugar binding antibody U61: the addition of inulotriose perturbs very few resonances, with the area in the difference spectrum corresponding to approximately 20 protons. Figure 4 compares the aromatic region difference spectra for inulotriose binding to E109 and U61, and indicates that these antibodies have very similar binding sites (see Section 3).

In this article we summarize the main conclusions of our work on three main types of binding sites. These are the DNP binding M315, for which a structure has been predicted, the phosphorylcholine binding M603 for which X-ray data are available, and the sugar (inulotriose) binding E109 and U61 for which only qualitative conclusions are made.

2 THE DNP BINDING IgA (λ_2) MOUSE PROTEIN—M315

The binding site is shown in Figure 5, with DNP-glycine in the site. The main results from our studies on this myeloma are listed below, and the techniques used in each case are shown in parentheses. Further details can be found in the appropriate references.

1. The combining site has a depth of 1.1–2 nm and lateral dimensions of 0.08×1.1 nm. The entrance to the site is

Figure 3 (a) Proton NMR spectrum at 270 MHz of the Fab (1.5 mM) of U61 and (b) the difference spectrum ($\times 2$) after addition of 1:1 inulotriose (Glc_p1-1 fruc_f 2-1 fruc_f, p = pyranose, f = furanose ring) ($\text{pH}^+ = 7.08$ and $T = 303 \text{ K}$)

Figure 4 Proton NMR aromatic region at 270 MHz of Fab of (a) U61, (b) U61 difference spectrum ($\times 2$) with inulotriose, and (c) E109 difference spectrum with lotriose

symmetric with respect to the plane of the DNP ring. The DNP ring is rigidly held as judged from the ESR timescale, $\sim 1 \text{ ns}$. (ESR mobility mapping.)¹⁶

- Arg95_L and His102 (not shown in diagram) are located at the entrance to the site. (ESR mobility mapping, ³¹P NMR, pK_a mapping, ¹H NMR difference spectroscopy.)¹⁷
- The DNP binding site is highly aromatic, the hapten being contained in an aromatic box of amino acid residues assigned to Trp93_L, Phe34_H, Tyr34_L, and Tyr33_H. (Proton NMR spectroscopy, ring current calculations, model building, ultraviolet absorption, and in vivo deuteration.)^{18,19}
- Tyr34_L and Tyr33_H interact with suitable side chains of the DNP ligands. In DNP-glycine, Tyr33_H is in van der Waals contact with the CH₂ group. (Proton NMR spectroscopy, chemical modifications of individual chains and formation of recombinant antibody molecules, pK_a mapping.)^{20,21}
- The major interactions of the haptens are with the light chain. The environments of these contact amino residues

Figure 5 Postulated refined structure of the binding site of M315, with DNP-glycine. Note the key residues Trp93_L, Phe34_H, and Tyr33_H, and the possible polar contacts between Asn36_L, Asn36_H, and the two nitro groups of the hapten

around the DNP ring are not perturbed by substitution of a V_H domain by a V_L domain. [Preparation of light chain variable region dimers (V_L)₂. Proton NMR difference spectroscopy.]²²

- The free energy of interaction of the DNP ring with Trp93_L is $-14.6 \text{ kJ mol}^{-1}$. (Proton NMR.)²³
- The nitro groups of these haptens are involved in specific interactions with the protein (possibly Asn36_H and Asn36_L). The strength of these are $4-8 \text{ kJ mol}^{-1}$. (Laser Raman spectroscopy on ¹⁵N enriched haptens, ¹⁵N NMR, ¹H NMR difference spectroscopy, substitution of nitro groups by chlorine, model building, chemical modification.)^{24,25}
- The combining site has a broad range of specificity for aromatic compounds—there is no evidence for multiple binding sites. (Fluorescence, ¹H NMR difference spectroscopy.)^{13,15,26}
- There is very little structural change on hapten binding. However, there are resonances arising from residues in or near the combining site that may be exchange broadened. The timescale for the exchange when combined with the interpretation from T jump experiments would suggest that conformational changes are localized in the binding sites. (Proton NMR difference spectroscopy.)²⁷
- The combining site is identical in the IgA, Fab, and Fv fragments. (Proton NMR difference spectroscopy.)²⁸

Figure 6 Side view of the arrangement of Trp93_L and Phe34_H in the combining site of M315 for (a) DNP-aspartate (b) TNP-glycine, and (c) dinitronaphthol-7-sulfonate. These haptens are representative of the range of haptens that bind to M315. All bind in the site with only minimal adjustments in the positions of the proteins side chains

11. By using the concept of framework invariance in immunoglobulins, a model of the combining site of M315 was generated using the X-ray coordinates of the immunoglobulin fold and the sequence of M315.¹¹ Figure 5 shows the refinement of this model²⁸ using the NMR and other physical data. In this way, residues forming the binding site were thus assigned.
12. In this model, haptens of different size and shape may be accommodated in the site, in a way which is compatible with the experimental data and require only minimal adjustments in the position of the protein side chains. Figure 6 gives the arrangements of Phe34_H and Trp93_L for DNP-aspartate, TNP (2,4,6-trinitrophenyl)-glycine, and dinitronaphthol-7-sulfonate, which are representative of the entire range of haptens studied.

We also concluded that the specificity is essentially a shape problem with the additional possibility of hydrogen bonding to the two nitro groups. The major binding energy appears to come from desolvation of the aromatic hapten. This would account for the broad range of aromatic binding specificity.

The very detailed studies involved here were necessary in attempting to establish the general method and to make as rigorous as possible the NMR interpretations. This also entailed work on model systems, in particular lysozyme, to check the basis of the ring current calculations used in structure analysis. New ring current calibrations for tryptophan residues were obtained,²³ and their use will be of general importance in the NMR studies of proteins.

Although the detailed X-ray model of the binding site is not yet available, it is of interest to note the following from the D.Phil. thesis of Bannock:¹⁴

It can be concluded that the current X-ray model of the site is completely consistent with the biophysical data, and confirms the validity of the assumption about the spatial distribution of the hypervariable loops on the basis of which the NMR site was constructed. This result means that it is entirely feasible to combine the two sources of information in a semi-predictive approach to the modelling of antibody combining sites.

3 THE PHOSPHORYLCHOLINE BINDING IgA M603

The refined X-ray structure is shown in Figure 7. Our NMR studies were confined to the Fab fragment, and our intention was to investigate the various subsites. Thus, we used ³¹P NMR studies on the two phosphorus nuclei of the phosphonium analog ($\text{Me}_3\text{P}^+\text{CH}_2\text{CH}_2\text{OPO}_3^{2-}$) of phosphorylcholine to monitor the charged subsites and the ¹H NMR to position the aromatic rings in the choline subsite.²⁷ Our results were as follows:

1. The pK_a of the phosphate groups are decreased by 0.5 units on binding to M603. This is consistent with the phosphate group being hydrogen bonded to Tyr33_H and Arg95_L, as suggested from the X-ray structure (Figure 6). The decrease in pK_a also implies that the binding energies for the mono- and dianion are similar.
2. The P^+Me_3 moiety probes the electrostatic interactions in the choline subsite. Titration of the ³¹P chemical shift of the phosphonium phosphorus reflects a group on the protein which has a pK_a value <5—which from the refined X-ray structure of the site is assigned to Asp97_L.
3. The choline subsite is monitored using ¹H NMR difference spectra, which indicate that the subsite is highly aromatic. This is as expected from the crystal structure, which places Trp107_H and Tyr100_L in this subsite. The ring current interactions from these rings can account for the ¹H NMR chemical shift data on choline.

All the NMR results are consistent with the major interactions between hapten and antibody as suggested on the basis of the crystal structure. This therefore provides an important control for the NMR method.

Finally, we note that our binding studies and those of other workers again indicate that the specificity is mainly a 'shape problem' and that, as expected, the binding energy, has a significant electrostatic contribution in this class of antibodies.

Figure 7 Hapten contact residues in M603 (kindly supplied by Dr. D. Davies) on the coordinates from the refinement at 0.27 nm together with a 0.31 nm difference Fourier map from the phosphorylcholine complex. The numbering system is that of Davies, and differs somewhat from the immunologists' numbering system

4 THE SUGAR BINDING IgA MOUSE MYELOMAS U61 AND E109

Saccharides form a widely distributed and very important class of naturally occurring antigens.¹⁵ Little structural data were available on E109 and U61 and at the time when the experiments were carried out, even the sequences were not complete. However, several general conclusions emerged from the NMR studies (the techniques used are given in parentheses):

1. There was little structural change in the protein on binding inulotriose to E109 and U61 (¹H NMR difference spectra—see Figures 3 and 4).
2. The binding sites were highly aromatic (¹H NMR difference spectra).
3. The combining sites of E109 and U61 were almost identical (Figure 4) (¹H NMR difference spectra).
4. The sugars may be internally hydrogen bonded (¹³C NMR).
5. The combining site appears to be composed of distinct subsites (binding studies).

Three distinct interactions expected to contribute to the thermodynamics of association of neutral oligosaccharides with antibody combining sites: hydrophobic, hydrogen bonding, and van der Waals. We suggest the importance of aromatic residues in the combining sites for D-sugars arises, in part, from the sugars adopting a ⁴C₁D conformation, in which there is a planar hydrophobic face. This can interact with the planar rings of the aromatic residues to form favorable hydrophobic contacts (Figure 8). Support for the concept that sugars can form hydrophobic interactions with aromatic amino acids can be found from the X-ray crystallographic studies on the Fc fragment of IgG and from similar work on the lysozyme–sugar complex. Sugars in aqueous solution will be extensively hydrogen bonded with the solvent. The simple transference of these hydrogen bonds with solvent to an array within a combining site which is itself extensively hydrated would not be expected to contribute significantly to the energetics of association. However, an important contribution may be envisaged

if the hydrogen bonds of the complex were formed in an environment of low dielectric constant such as may well arise in a combining site comprised predominantly of nonpolar amino acids. The third factor, van der Waals interaction, is difficult to estimate for sugars at the present time.

A basic difference between sugar and nonsugar binding proteins is the concept of distinct subsites in the former. The shape and topology of these subsites will determine the specificity for a particular sequence of sugars. An individual subsite which may be aromatic might not distinguish between sugars and other hydrophobic (e.g. aromatic) ligands which have the correct shape. The specificity of sugar binding proteins such as those studied here will therefore arise from the presence of several subsites (shown by the increasing strength of binding of the tetra- and trisaccharides compared with that of the monosaccharide). This was also true in lysozyme, where, for instance, trisaccharides bind three orders of magnitude more strongly than the monosaccharides. These subsites, therefore, favor carbohydrate antigens which are frequently polymeric and discriminate against smaller, hydrophobic ligands, which bind to an individual subsite but with relatively low affinity.

5 CONCLUSIONS AND FUTURE STUDIES

Antibody specificity for haptens is essentially a 'shape' problem involving the three-dimensional complementarity between the haptens and the amino acid residues in the combining sites. The combining site comprises a cleft or groove constructed from two distinct chains. Different antigens alter their position within the combining site to maximize noncovalent interactions. If the antigen has the correct shape it will fit into the site, but the actual binding energy depends on the extent of complementarity that can be obtained.

X-ray crystallographic studies have confirmed the idea that the structural mechanism used to generate the diversity of antigen binding sites is a conserved framework, the immunoglobulin fold, to which the hypervariable sequences which form the antigen binding site are attached. It is now considered feasible to construct models of immunoglobulin combining sites for which no X-ray studies exist, on the basis of their presumed homology with known structures. Further aspects of antibody specificity may then be investigated by use of these models, which can be tested and refined by NMR. In NMR the resolution of pairwise interactions is often better than 0.05 nm, and frequently at this resolution details of specificity are required. This means that NMR studies can also complement X-ray studies on combining sites.

Current studies involve the binding specificities of antibodies for protein molecules. For instance, how much of the surface of an antibody molecule or of the protein antigen is involved in binding to an antigenic site on the protein? Also, proteins, in contrast to small haptens or ligands, can have multiple antigenic binding sites. This means that the total immune response to even a small protein may involve multiple specificities. A study of the molecular basis of antibody recognition of a protein must be approached in terms of specific binding sites. The method of choice is to use monoclonal antibodies that can be sequenced and structurally studied.

The development therefore by Milstein and colleagues of the cell fusion technique for producing monoclonal antibodies

Figure 8 Diagrammatic representation of the hydrophobic face of sugars in the 4C_1D conformation. This hydrophobic face can interact with planar hydrophobic residues in the site. Sugar binding proteins usually have distinct subsites

of defined specificity and class still has immense potential for the study of antibody specificity and function and for providing diagnostic therapeutic tools for medicine. The ability to sequence rapidly at the DNA level, and the possibility of structure prediction and testing (or even filtering) by NMR with other physical methods will be complementary techniques for studying the functional aspects of not only the molecular basis for immune recognition but also of any class of receptors to which antibodies can be raised.

Acknowledgments

The decision to study antibodies by NMR was inspired by the late Professor R. R. Porter, the Nobel Laureate, who was Head of the Department of Biochemistry during the time of this work. To him and to all my colleagues who worked with me on the project, I owe an immense debt of gratitude. Likewise, I feel a debt of gratitude to my colleagues in Oxford who in the early years from 1970 onward helped pioneer the use of NMR in biology. Amongst those were Rex Richards, David Phillips, George Radda, Iain Campbell, and Bob Williams.

1 INTRODUCTION

High-resolution NMR can be used for determining structures of small biomolecules in solution.¹ Such studies are based upon the measurement of interactions between protons. The NOE, the origin of which is dipolar cross relaxation between protons, is especially crucial since it can be used to determine distances between closely spaced protons. The other proton–proton interaction is the J coupling, which is used to identify spin systems during the resonance assignment stage but which can also give information on torsion angles and, in this way, leads to more accurate structures. For small biomolecules these proton–proton interactions are most conveniently measured by 2D NMR techniques.² Thus, the J coupling manifests itself as cross peaks in COSY and TOCSY (or 2D HOHAHA) spectra and the NOE as cross peaks in NOESY (or 2D NOE) spectra.

Except for some favorable cases, however, 2D NMR studies have been limited to small biomolecules with molecular masses of less than 12 kDa. Several problems arise with larger molecules. Both the number of proton resonances and the resonance linewidth increase with size. This leads to overlap of resonances, which prohibits the unambiguous assignment of 2D cross peaks to specific proton pairs. The spectral resolution can be increased by adding a third^{3–8} or even a fourth frequency domain.^{9,10} In this way, overlapping protons can be characterized with the additional frequency of an associated nucleus that will help in establishing the interpretation of cross peaks. An extra complication is, however, that due to the increase in linewidth for large biomolecules, it becomes more difficult to observe small proton–proton J couplings and that magnetization transfer in 3D spectra based on such J couplings becomes weak. This disadvantage may be overcome in homonuclear 3D NOESY–NOESY spectroscopy,¹¹ but the complexity of the 3D NOESY–NOESY spectra can be

high and their sensitivity low. More recently, a number of heteronuclear 3D experiments have been developed, such as 3D NOESY–HMQC, 3D TOCSY–HMQC^{12–15} and 3D triple resonance techniques for (¹³C, ¹⁵N) doubly labeled molecules.^{16,17}

These heteronuclear techniques overcome the aforementioned problems, because they rely on strong heteronuclear J coupling constants and because the magnetization transfer is unique in many cases. The sensitivity of heteronuclear 3D and 4D experiments can be high and the spectral complexity low, and there is no doubt that for large biomolecules such methods are preferable to the homonuclear ones. However, the heteronuclear techniques have one clear disadvantage. They require that the biomolecular material is enriched in ¹³C, ¹⁵N or both isotopes, which is problematic if the material can only be obtained in low yields or if the biomolecule cannot be isolated from cell cultures. This applies to a large group of very interesting biomolecules, including glycoproteins, oligosaccharides, and oligonucleotides.

Several reviews on multidimensional NMR techniques have appeared, and a thorough account of various theoretical and practical aspects of 3D NMR has been given by Griesinger et al.¹⁸ Triple resonance techniques for studies on (¹³C, ¹⁵N) doubly labeled proteins have been reviewed thoroughly by Clore and Gronenborn¹⁹ and by Bax and Grzesiek.²⁰ A recent survey was provided by Oschkinat et al.²¹ Our main focus will be homonuclear 3D NMR of biomolecules (see *Three- and Four-Dimensional Heteronuclear Magnetic Resonance* and *Three-Dimensional HMQC-NOESY, NOESY-HMQC, and NOESY-HSQC*).

2 WHY HIGHER DIMENSIONS?

Most interactions in NMR spectroscopy are pairwise by nature. In principle, two frequency domains and, thus, 2D NMR should suffice to establish such pair interactions between magnetic nuclei.²² Certainly for large biomolecules, however, there is a high chance of overlap for resonances of different nuclei. In that case 2D relayed experiments have been proposed, where the magnetization is transferred from the second overlapping nucleus to a third one via an additional mixing step.^{23,24} Both homonuclear and heteronuclear coherence transfer steps can be used to resolve ambiguous NOEs in a new frequency domain.^{25–28} For small biomolecules the comparison of resonances in the direct domain of the original 2D experiment and the indirect domain of the 2D relay experiment is in many cases sufficient to resolve most ambiguities.²⁹ However, for large molecules it is likely that a new overlap exists in this indirect domain. This overlap may then be resolved by a simultaneous registration of the direct and the relayed frequencies. In this way a 3D spectrum is created where overlap for the receiving nuclei can be resolved (Figure 1). If overlap exists for the originating nuclei, the magnetization in their domain may also be relayed. Modulation at both the direct and the relayed frequencies for the originating and the receiving nuclei would lead to a 4D spectrum. Higher dimensionality is probably not practical.^{20,22}

In multidimensional NMR one can distinguish between the interactions of interest and those that are suitable for relaying the information to other frequency domains. The structure

Figure 1 Illustration of the increase in resolution due to the increase in dimensionality. In the 2D spectrum four cross peaks overlap. By correlation with a third resonance frequency each cross peak achieves a different position along a line in the 3D spectrum, thus resolving the overlap problem

determination of biomolecules is mainly based on the interpretation of proton–proton NOEs, while for the prerequisite assignment of proton resonances considerable use is made of J coupling data. Therefore, it is of great importance to establish the absence and presence of these interactions unambiguously. Optimally, the frequencies connected by the relayed transfer are not linearly correlated, the relayed nuclei involved are abundant, the transfer will be very efficient introducing only low signal losses, all proton resonances can be relayed, and the relay interaction can be interpreted uniquely. In practice this is not the case, but the requirements are best met by combinations of various heteronuclear 3D and 4D experiments on (^{13}C , ^{15}N) doubly labeled compounds. When isotope labeling is not possible, however, homonuclear 3D methods may be preferable, but the analysis of the resulting spectra can be complex. A large part of this review will summarize methods for analyzing such homonuclear spectra.

3 CLASSIFICATION OF MULTIDIMENSIONAL NMR EXPERIMENTS

Over the years many pulse sequences have been proposed to establish homonuclear and heteronuclear interactions between pairs of nuclei.² Of course, all these pair transfers can be used as building blocks of multidimensional NMR experiments. The interactions in high-resolution ^1H NMR can have a coherent or an incoherent nature. Incoherent sources for interaction are kinetic exchange and dipolar cross relaxation, while the homonuclear and heteronuclear J couplings have a coherent nature. Two types of 2D experiments can be discriminated by which these processes can be measured: the large COSY family for identifying J interactions within spin systems^{2,30} and the 2D exchange or NOE category for the analysis of kinetic equilibria,³¹ NOESY,^{32,33} and ROESY^{34,35} effects. Most 2D experiments involve magnetization transfer due to a single type of interaction and thus will fall in one of these two categories. Most 3D experiments (but also relayed 2D experiments) should then belong to combinations of these two. The basic categories for double transfer will be J – J , J –NOE, NOE– J , and NOE–NOE. Of these, the J –NOE and NOE– J type experiments will contain the same information and can be brought into one category. It is obvious that one can classify 3D COSY–COSY,^{5,6} 3D COSY–NOESY,⁶ 3D NOESY–TOCSY experiments,^{7,8} or

3D NOESY–ROESY in one of these groups. Of course, with 4D spectroscopy, or better triple transfer techniques, eight (but only six unique) classes can then already be defined, and for quadruple transfer experiments even 16. In general it can be anticipated that the J – J and J – J – J type experiments should be useful for assignment purposes, while triple transfer J –NOE– J type experiments can be helpful for identifying NOEs.

It is clear that by combination of the ‘building blocks’ used in 2D spectroscopy a countless number of different types of experiments can be constructed.

4 THE DESIGN OF MULTIDIMENSIONAL HOMONUCLEAR EXPERIMENTS

Each multidimensional experiment will start with a preparation period. Generally, this is a delay to bring the spin system to Boltzmann equilibrium followed by a 90° rf pulse. This will be followed by one or more evolution periods and a detection period, all separated by magnetization transfer steps similar to those in two-dimensional NMR. The experiments can be designed by the appropriate combination of two 2D NMR pulse schemes. A 3D NMR experiment can be regarded as the combination of two 2D experiments, in which the detection period of the first experiment has been replaced by the evolution, mixing, and detection periods of the second.⁵ For example, a NOESY and TOCSY experiment can combine to form a 3D NOESY–TOCSY experiment.^{7,8} As shown in Figure 2, the FID in the time domain t_3 is then recorded as a function of two variable times t_1 and t_2 , which are independently incremented. After Fourier transformation in the three dimensions a 3D NMR spectrum is obtained with three independent frequency axes. A cross peak in the 3D spectrum arises when magnetization of one proton is transferred during the first (NOE) mixing period to a second proton and then during the second (TOCSY or HOHAHA) mixing period to a third one. Figure 3 shows a number of 3D pulse schemes and their division into preparation, evolution, and mixing periods, but basically the same principles apply to all experiments.

In 3D experiments using TOCSY, NOESY, and ROESY mixing periods the magnetization is transferred not to one but to a number of other spins. Therefore, the J or NOE interactions can be observed at a number of 3D cross

Figure 2 (a) Pulse sequence for a 3D NOESY–TOCSY experiment, constructed from (b) a 2D NOE experiment, and (c) a TOCSY experiment with a MLEV-17 mixing sequence

Figure 3 Pulse sequences for homonuclear 3D experiments

peaks. A coincidental overlap at one 3D cross peak can then be overcome by another nonoverlapping one. However, the disadvantages of such an approach are an increase in complexity of the 3D spectra and a reduction of signal intensity by dilution. 3D spectra which use COSY-like relays, where magnetization is transferred to one other nucleus only, lead to spectra which are much more amenable for analysis. However, for protons the $^3J(\text{H}, \text{H})$ coupling, which forms the basis for the COSY magnetization transfer, is relatively weak, and the necessary development of antiphase magnetization during the evolution and acquisition periods can take a long time compared with the T_2 relaxation time. This makes 3D experiments involving a proton-proton COSY transfer insensitive for biomolecules with a short T_2 , and the long sampling of the t_1 or t_2 evolution periods may create excessively long recording times. The favorable J magnetization transfer induced by the HOHAHA effect is much more suitable for homonuclear 3D experiments of biomolecules. For large (>20 kDa) biomolecules the HOHAHA transfer can also become weak. In order to avoid complex analysis the selectivity of a relayed HOHAHA or a relayed NOE transfer may be optimized by choosing a relatively short mixing time. Other suitable building blocks for homonuclear 3D experiments of biomolecules are NOESY (or EXSY) and ROESY mixing periods.

5 SELECTIVE AND NONSELECTIVE HOMONUCLEAR 3D NMR

Since both the t_1 and t_2 domains of a 3D experiment (see Figure 2) have to be incremented independently, a large number of FIDs are recorded in order to obtain a sufficiently high resolution for these two domains. In principle, this could lead to long measuring times and to practical problems in handling large data sets.

Reduction of measuring time, the amount of collected data or a need for high digitization in a selected spectral area may require that the frequency sampling in the t_1 and t_2 domains is limited by means of using semiselective rf pulses which excite only a small portion of the NMR spectrum.⁵⁻⁷ In this way one zooms in, as it were, onto a part of the complete 3D spectrum. Most of the early examples of homonuclear 3D experiments were semiselective: the semiselective COSY-COSY,^{5,6} the semiselective NOESY-COSY,⁶ and the semiselective NOESY-TOCSY.^{7,36,37} The 3D J -resolved experiments^{3,4} fall in a slightly different category, since they do not correlate chemical shifts across all mixing periods, but here also the recording time is relatively short. As in 2D J -resolved spectroscopy the aim of such experiments is the separation of chemical shifts and scalar (or dipolar) interactions, which may require a very different digitization.

In the nonselective 3D NMR experiments,⁸ only hard pulses are used for the t_1 and t_2 domain, which allows for a complete sampling of all frequencies in the three dimensions. Although prolonged measuring times can be anticipated, some gain is obtained through the relative simplicity of the rf pulse sequences which makes short phase cycling schemes possible. In fact, most of the nonselective homonuclear 3D NMR experiments can be carried out within 2–5 days.

In terms of analysis, however, the semiselective and nonselective 3D NMR techniques are similar.

6 PRINCIPLES OF HOMONUCLEAR 3D SPECTROSCOPY

The 3D NOESY-TOCSY spectrum recorded with the pulse scheme of Figure 2 and obtained after 3D Fourier transformation of the FIDs can be schematically presented as a cube with three frequency axes, f_1 , f_2 , and f_3 . In a 3D spectrum obtained in this way, a body diagonal ($f_1 = f_2 = f_3$) can be identified, which contains magnetization that was not transferred during any of the mixing periods. Additionally, intensity accumulates on the three cross-diagonal planes, which is shown in Figure 4. In the case of the 3D NOESY-TOCSY experiment, the plane $f_2 = f_3$ (NOE plane) contains magnetization transferred only during the first (NOE) mixing period, whereas the plane $f_1 = f_2$ (TOCSY or HOHAHA plane) contains magnetization transferred during the second (HOHAHA) mixing period. Finally, the plane $f_1 = f_3$ (back-transfer plane) contains magnetization that was transferred during the first (NOE) mixing period from proton a to proton b and then back to proton a during the second (HOHAHA) mixing period. For the analysis of 3D NMR spectra, cross sections perpendicular to one of the frequency axes can be used. Figure 5 shows an f_1 - f_2 plane (which is perpendicular to the f_3 axis). The three diagonal planes of

Figure 4 Cross-diagonal planes in a 3D NOESY-TOCSY spectrum: (a) NOE plane, (b) HOHAHA or TOCSY plane, and (c) back-transfer plane

Figure 5 Schematic representation of an f_1 - f_2 plane, perpendicular to the f_3 axis. The NOE, HOHAHA and back-transfer lines constitute the intersection with the three planes indicated in Figure 4

Figure 4 intersect this plane at the three lines indicated as NOE (or N), HOHAHA (or H) and back-transfer (or B) lines. These lines all share one point on the body diagonal of the spectrum.

Cross peaks that are present on the NOE and HOHAHA lines in the cross section taken at $f_3 = f_a$ represent single step magnetization transfer (by NOE and HOHAHA, respectively) to a proton a . Hence, the 3D NOESY-TOCSY spectrum contains the information that is present in traditional 2D NOESY and TOCSY spectra as a subset. All cross peaks outside the NOE and HOHAHA planes are due to double magnetization transfer. The double magnetization transfer that gives rise to peaks in the back-transfer plane is unique for homonuclear 3D experiments, since both mixing periods cover the same spectral frequencies. The closest 2D analogues of 3D NOESY-TOCSY experiments are relayed NOESY experiments^{25,26} 2D TOCSY-NOESY,²⁷ and 2D ROESY-TOCSY and TOCSY-ROESY.²⁹ The information content of such spectra is present in the 3D spectrum as a projection onto the f_1 - f_3 groundplane. However, since the cross peaks are labeled by three different frequencies, fewer ambiguities will arise in a 3D spectrum.

Figure 6 shows the nonselective 3D NOESY-TOCSY spectrum of a 109 residue protein, parvalbumin, in $^1\text{H}_2\text{O}$. The spectrum contains a large number of cross peaks. Most of the intensity accumulates on the body diagonal and the NOE

Figure 6 3D NOESY-TOCSY spectrum of a 109-residue protein in $^1\text{H}_2\text{O}$. The spectrum shows local intensity maxima for most cross peaks. The data set was recorded in 171 h at 500 MHz using an eight-scan phase cycle, as described by Vuister et al.⁸ The NOE mixing time was 150 ms and the HOHAHA mixing time was 47 ms. The data were processed to a resolution of $256 \times 256 \times 256$. The sample contained 8.7 mM pike parvalbumin at pH = 4.1, 315 K, 10% D_2O .⁸ (Reproduced by permission from Vuister et al.⁸)

and HOHAHA planes. Less intensity accumulates on the back-transfer plane, because the associated magnetization must have gone through a double transfer. Intensities at positions ($f_1 \neq f_2 \neq f_3$), i.e. not on the three diagonal planes, correspond to magnetization which was transferred during both mixing periods. Figure 7 shows a contour plot of the NOE plane of the same 3D spectrum. This plot is very similar to a contour plot of the NOESY spectrum of this protein and indicates the need to increase the resolution for proteins of this size by using a third domain. Similarly, the HOHAHA plane resembles a TOCSY spectrum.

The analysis of 3D spectra can be accomplished in planes perpendicular to any axis of the 3D spectrum. In Figure 8(a) the flow of magnetization is sketched as observed in an f_1 - f_2 plane of a 3D NOESY-TOCSY experiment. A cross peak at (f_a, f_b, f_c) indicates that magnetization started on a nucleus with frequency f_a was transferred by NOE to a nucleus with frequency f_b and was then transferred by isotropic mixing to a nucleus at f_c on the diagonal. Figure 8(b) shows the same flow in an f_2 - f_3 plane, but now the magnetization originates from the diagonal. Finally Figure 8(c) shows this flow in an f_1 - f_3 plane. The flow in a TOCSY-NOESY spectrum goes in the opposite direction, and the same planes can be constructed for the equivalent cross peak (f_c, f_b, f_a). Figure 8(d), 8(e) and 8(f) show the equivalence of the f_2 - f_3 , f_1 - f_2 , and f_1 - f_3 planes of a 3D TOCSY-NOESY spectrum with that of the f_1 - f_2 , f_2 - f_3 , and f_3 - f_1 planes of a 3D NOESY-TOCSY spectrum, respectively. Only the flow, as indicated by the arrows, is inverted, while the appearance of the spectrum is the same.

Figure 7 NOE plane of a 3D NOESY–TOCSY spectrum of the 109-residue protein of Figure 6. (Reproduced by permission from Vuister et al.⁸)

The cross peaks in 3D spectra reflect connectivities between the spins. To describe the connectivities the C notation can be used: $C[M_1, M_2]_{abc}$ (i, j, k) or shorthand C_{abc} (i, j, k) means that magnetization of proton a in residue i is interacting via mixing step M_1 with proton b of residue i and next via mixing step M_2 to proton c of residue k . Thus, 3D NOESY–TOCSY and 3D TOCSY–NOESY spectra contain the same connectivity information: a $C[\text{NOE}, J]_{abc}$ (i, j, j) pathway is equivalent to a $C[J, \text{NOE}]_{cba}$ (j, j, i) pathway. Both represent the same combination of interactions. Experimentally, however, differences in t_1 and t_2 noise and in domain resolution make it quite different, whether a $C_{\text{NN}\alpha}$ ($i + 1, i, i$) connectivity is observed in an f_1 – f_2 plane at f_3 of the α proton (such as in 3D NOESY–TOCSY) or at f_3 of the NH proton (as in 3D TOCSY–NOESY).

7 PRACTICAL ASPECTS

7.1 Sensitivity

For 3D spectra a better signal-to-noise ratio is required than that of the 2D analogs, since the aim of 3D experiments is the observation of weak double magnetization transfers. Therefore, 3D techniques should only be applied in case of overlap in optimally recorded 2D spectra.

The sensitivity of a 3D experiment is determined by the efficiency of magnetization transfer in the mixing periods, by T_2 relaxation during the evolution and acquisition periods, and the method of selecting the evolved magnetization. As in 2D spectroscopy most mixing periods select only the x or y component of the magnetization from the previous evolution period, and by phase cycling the other term is removed. This leads to the loss of half of the magnetization

and half of the noise power. Therefore, as pointed out by Bax and Grzesiek,²⁰ each addition of dimensionality may lead to a signal-to-noise reduction by $1/\sqrt{2}$. This loss in the signal-to-noise ratio can, however, be avoided by retaining both orthogonal magnetization components across the mixing periods (see Cavanagh and Rance³⁸ for a review). This method has been applied to 3D NOESY–TOCSY.³⁹ A drawback may be, however, an increase in experiment time due to additional phase cycling in order to obtain phase-sensitive spectra.

In 3D spectroscopy the signal accumulates independently in all domains. By minimizing the length of the evolution periods, loss of sensitivity due to T_2 relaxation can be avoided. The length of the evolution periods should be only so long that overlap of cross peaks is avoided, or as required for the further analysis of the 3D spectra. Since there is a lower chance of overlap in 3D than in 2D spectra the evolution periods can clearly be shorter in 3D spectra. With the crowded spectra of biomolecules, however, it is difficult to predict which resolution is finally needed until the analysis is completed. As a guideline it is noted that sampling with the evolution periods beyond $0.9T_2$ is only to increase resolution, while sampling below $0.9T_2$ will add signal to the multidimensional cross peaks. The sensitivity of the NOE and HOHAHA planes of an optimally recorded 3D NOESY–TOCSY spectrum will be similar to that of the two 2D counterparts recorded together in the same total time. However, the aim of a 3D experiment is clearly the observation of double magnetization transfer, and the corresponding cross peaks will be much weaker.

For good sensitivity of multidimensional experiments it is extremely important to optimize the transfer efficiencies of the mixing periods. For TOCSY, various improvements have been published, compensating relaxation by ‘clean’ TOCSY pulse sequences⁴⁰ or increasing sensitivity by orthogonal magnetization transfer, as discussed above. For ROESY, potential J transfer should be minimized.³⁵ For NOESY no fundamental optimizations are possible, but accurate and homogeneous 90° rf pulses will enhance the transfer. In all cases the transfer efficiencies may be optimized by adapting the length of the mixing period. Since the cross-peak intensity in 3D spectroscopy is proportional to the product of the constituent 2D transfer efficiencies, an optimal 2D mixing time will also be the optimum for three dimensions.

Another important factor for sensitivity is the number of rf pulses in combination with pulse imperfections, i.e. inaccurate flip angles or B_1 inhomogeneities. Generally, phase cycles of 2D and 3D experiments are set up so that only coherences are selected which pass the sequence assuming ideal 90° and 180° pulses and that coherences created by the imperfections are suppressed. Since most homonuclear 3D sequences contain only a few rf pulses or a self-compensated isotropic mixing period, only a small amount of magnetization is lost in this way.

However, in many cases the actual sensitivity is less favorable due to t_1 and t_2 noise caused by instrument instabilities. Such instabilities are present in 2D spectroscopy as well, but the 3D technique may sample additional instabilities due to the length of the experiment and the wish to minimize recording time. On some NMR instruments undefined delays may be introduced between the FIDs. A constant steady state magnetization may be maintained by a buffered acquisition method or by steady state pulses.

Figure 8 Flow of magnetization for a cross peak (f_a, f_b, f_c) in a 3D NOESY-TOCSY spectrum and the equivalent cross peak (f_c, f_b, f_a) in a 3D TOCSY-NOESY spectrum. (a)–(c) The f_1 - f_2 , f_2 - f_3 , and the f_1 - f_3 planes of a 3D NOESY-TOCSY spectrum. (d)–(f) The f_2 - f_3 , f_1 - f_2 , and the f_1 - f_3 planes of a 3D TOCSY-NOESY spectrum. The lines indicated by N, H, and B are the cross-diagonal NOE, HOHAHA (or TOCSY), and back-transfer lines, respectively. Only the flow of magnetization in the two spectra reverses; the appearance of both spectra is the same

Fluctuations in the extent of sample heating due to the pulse sequence are more difficult to avoid.

7.2 Phase Cycling and Recording Time

Both phase cycling or field gradients can be used for selecting the coherence transfer pathway in 3D experiments. Since the gradients do the selection in single experiments, use of gradients is preferable for 3D spectroscopy. Thus, the NOE effect can be selected by a single gradient pulse in the NOE mixing period.³¹ However, the number of phase cycling steps can also be minimized in 3D spectroscopy. For large biomolecules the phase cycling to select NOE mixing can be short, since most undesirable coherences have decayed at the end of the NOE mixing time. Suppression of single quantum coherences is normally sufficient and can be accomplished by two phase steps. The HOHAHA mixing requires no selection of coherence level at all, if a 'clean' MLEV sequence is used.⁴⁰ Axial peaks due to T_1 relaxation can be suppressed by inversion of the first 90° rf pulse, which will double the phase cycle. Inaccurate 90° or 180° rf pulses may lead, however, to an axial plane at the f_1 – f_3 ground plane of a 3D spectrum, which can be removed by inverting all pulses before the t_2 period. In order to separate positive and negative frequencies in the t_1 and t_2 domains, either a time proportional phase increment (TPPI) or a States–TPPI sampling scheme should be used, which will put potential axial peaks at the sides of the 3D cube. Homonuclear 3D spectroscopy with minimal phase cycling has been demonstrated for 3D NOESY–NOESY⁴¹ and for 3D TOCSY–NOESY.⁴² In practice, 3D TOCSY–TOCSY and gradient enhanced 3D TOCSY–NOESY with axial peak suppression in t_1 will have a minimal two-step phase cycle inverting only the very first rf pulse. Without gradients the minimal phase cycling for 3D TOCSY–NOESY becomes four and for 3D NOESY–NOESY already eight, while inclusion of axial plane correction brings this to eight and 16, respectively.

NMR receiver imperfections may require additional phase cycling in order to remove dc bias and quad-image artifacts, but they can be mixed into the phase cycle for coherence selection. Thus, depending on the level of artifact suppression needed, phase cycles of 1–6 scans can be used. Typically, 128–256 independent t_1 and t_2 increments are used to sample the corresponding domains, with an acquisition size of 512–1024 words. In order to reduce measuring time, the relaxation delay between each scan is set to a value close to the T_1 relaxation time of the biomolecule, which results in some saturation. In this fashion, the repetition rate per scan is about 1 s, and a typical $160 \times 256 \times 1024$ 3D TOCSY–NOESY experiment takes between 46 h for a four-scan and 182 h for a 16-scan version and will create 42 Mwords of data.

7.3 Processing

The heavily truncated interferograms in the t_1 and t_2 periods of 3D datasets are in principle not suitable for frequency analysis by fast Fourier transforms. Apodization functions such as the Hamming or Kaiser windows vastly decrease the amount of 'ripple' (cf. Ernst et al.²). A better approach is frequency analysis by parametric methods based on linear prediction^{43–45} and by the maximum entropy or Bayesian methods,⁴⁶ but these

methods can be computationally expensive. A more modest but practical approach is the extension of the experimental data set by linear prediction, followed by window multiplication and a fast Fourier transform.⁴⁷ Phasing parameters for the evolution periods can either be calculated from initial delay values and rf pulse widths⁴⁸ or estimated by visual inspection of the data. After the Fourier transform the 3D spectrum can be baseline corrected in all domains by a variety of methods.^{49,50} Offsets and baseline distortions in the f_1 and f_2 domains can, however, already be minimized by data sampling techniques.^{51,52}

For the manual analysis of 3D spectra, contour plots can be produced for all cross sections that contain cross peaks. This approach may be sufficient for settling overlap in crowded 2D spectra. Since bookkeeping of all peaks in a 3D spectrum can be cumbersome, analysis with a workstation is to be preferred. Programs have been developed that can assist the manual analysis of such spectra.^{53–56} A step further is the automatic or semiautomatic analysis of patterns of correlated cross peaks, e.g. for assigning 3D proton spectra.^{54,57,58} The input of such programs may require further processing of the spectra, e.g. searches of local maxima and peak boundaries, peak decomposition, and determination of intensities.

8 APPLICATIONS

8.1 3D J -Resolved Spectroscopy

The 3D J -resolved experiment can be visualized as a 2D J -resolved experiment in which the acquisition period has been replaced by the evolution period, mixing period, and acquisition period of a second 2D experiment. Both COSY^{3,4,59} and NOESY⁶⁰ have been suggested for this second experiment. Such 3D J -resolved spectra can become useful when overlap interferes with the analysis of multiplet patterns in a 2D J -resolved spectrum. A drawback of J -resolved spectroscopy for measuring J couplings as compared with ECOSY techniques⁶¹ is that the multiplet pattern is not simplified, but remains at full complexity. This explains the limited application of the method for high-resolution studies of biomolecules. Related 3D experiments in solid state NMR for separating chemical shift and dipolar interactions have found more extensive use.^{62,63} The 3D J -resolved method demonstrated, however, the feasibility of 3D NMR and started the development of a large number of other 3D techniques.

8.2 3D TOCSY–NOESY and 3D NOESY–TOCSY Spectroscopy

For most biomolecular studies both the J coupling and the NOE interaction must be measured. Such interactions can be obtained by separate NOESY and COSY or TOCSY experiments, but it is logical to combine both into one 3D experiment in which one mixing period contains the NOE effect and the other the J coupling. Two types of homonuclear experiments can be envisaged: 3D NOE– J and 3D J –NOE. The first implementation was shown by Griesinger et al.⁶ in a semiselective 3D NOESY–COSY experiment. However, for larger biomolecules the J effect is transferred much more efficiently by a HOHAHA mixing period, as was demonstrated

by Oschkinat et al.⁷ in a semiselective 3D NOESY–TOCSY experiment of a 46-residue protein. Shortly after, it was shown that complete nonselective 3D NOESY–TOCSY experiments of proteins can also be executed in a reasonable time.⁸ Later improvements used ‘clean’ MLEV sequences^{37,64,65} and orthogonal isotropic mixing³⁹ to enhance the amount of transferred magnetization.

8.3 Observation of Sequential NOEs in Proteins

The combined observation of J couplings and NOE interactions in 3D NOESY–TOCSY spectra makes it possible to assign the proton resonances in the protein spectrum by a similar sequential assignment strategy as developed by Wüthrich and his co-workers¹ for 2D spectra. In the 2D approach, the spin systems of the protons belonging to one amino acid residue are identified by exhaustively analyzing the through-bond proton–proton connectivities in COSY and TOCSY spectra. The sequentially neighboring amino acid spin systems are then identified by observation of the sequential d_{NN} , $d_{\alpha N}$ and $d_{\beta N}$ connectivities in 2D NOE spectra. Starting at a unique spin system or by matching unique di- and tripeptide sequences on the complete protein sequence, the spin systems can be assigned to specific amino acids. In a simplified view, the spin system analysis can be reduced to observing αN connectivities between the J -coupled α and NH protons of each amino acid residue, while the sequential assignment is based (among others) on αN connectivities between neighbors. In 3D NOESY–TOCSY and 3D TOCSY–NOESY experiments, we can measure both types of connectivity simultaneously in one $C[NOE, J]_{N\alpha N}(i+1, i, i)$ connectivity. In fact, two types of $N\alpha N$ connectivities exist: sequential $C_{N\alpha N}(i+1, i, i)$ and intraresidue $C_{N\alpha N}(i, i, i)$ connectivities. Both connectivities can be observed in the scheme shown in Figure 9. The intraresidue $C_{N\alpha N}(i, i, i)$ connectivity of residue i will be found on the back-transfer line of an f_1 – f_2 plane, whereas the sequential $C_{N\alpha N}(i+1, i, i)$ connectivity to residue $(i-1)$ will be found on a line parallel to the NOE line through the intraresidue $C_{N\alpha N}(i, i, i)$ connectivity. This then defines the NH f_3 frequency for the next f_1 – f_2 plane, where we can repeat the search for both connectivities. An example of such a sequential assignment is given in Figure 10 for the 3D NOESY–TOCSY spectrum of pike parvalbumin from Asp92 to Ile97.

Complete descriptions of the sequential assignment strategy using 3D NOESY–TOCSY or 3D TOCSY–NOESY spectra were given by Vuister et al.⁶⁶ and by Oschkinat et al.⁶⁷ A full analysis of all possible 3D sequential connectivities in proteins was given, and estimates of the relative intensities of cross peaks corresponding to such connectivities for α -helical and β -sheet conformations, as summarized in Table 1 (for α - and N-protons only). Thus, by searching the 3D spectrum for such connectivities it is possible to analyze the secondary structure of the protein.

The method has been applied to the 109 amino acid residue protein parvalbumin. Most of the sequential backbone cross peaks of this protein were observed⁶⁸ in a single 3D TOCSY–NOESY spectrum of parvalbumin. The assignment based on these 3D data corresponds completely with a previous one using extensive 2D data. Even some novel NOEs, hidden due to overlap in the 2D spectra of parvalbumin,

Figure 9 Sequential and intraresidue $C_{N\alpha N}$ connectivities in an f_1 – f_2 plane of a 3D NOESY–TOCSY spectrum. The lines indicated by N, H, and B are the cross diagonal NOE, HOHAHA (or TOCSY), and back-transfer lines, respectively. The two dotted arrows starting at a back-transfer cross peak indicate the intraresidue $C_{N\alpha N}(i, i, i)$ connectivity, where the first arrow represents the NOE transfer from N to α and the second one the J transfer from α back to N. The two solid arrows show the interresidue $C_{N\alpha N}(i+1, i, i)$ connectivity

could be identified. Similar results have been obtained for α -purothionin,³⁷ bovine pancreas trypsin inhibitor (BPTI),⁶⁷ the 113-residue protein aponeurocarzinostatin,⁶⁹ a 90-residue phospholipid transfer protein,⁷⁰ a 137-residue flavodoxin,⁶⁵ the 128-residue blue copper protein azurin,⁷¹ the 153-residue interleukin-4,²¹ and the monomeric 143-residue heme protein leghemoglobin.⁷² In most cases the analysis of the homonuclear 3D data led to additions or corrections in previously established assignments. The assignment for one residue was corrected for α -purothionin. Parvalbumin was shown to contain one amino acid residue more than expected on the basis of the amino acid sequence. For flavodoxin, 15 additional residues were identified from the 3D spectra. For neocarzinostatin it was possible to correct inconsistent assignments from three previous publications.

It is clear that the combination of NOE transfer and isotropic mixing in one 3D experiment is very useful in sequential assignment procedures of protein NMR spectra. Since the information is contained in one data set, these procedures may be better suited for automation than methods which rely on matching two different NOESY and TOCSY spectra. Furthermore, the increased resolution and the presence of the two-step connectivities will reduce overlap in spectra of larger biomolecules. Semiautomated approaches for analyzing 3D NOESY–TOCSY spectra of proteins have been demonstrated by Oschkinat et al.^{57,58} and Kleywegt et al.⁵⁴ In this latter procedure, sets of J -coupled resonances are obtained from a peak list of the 3D spectrum. These sets are then ranked as possible spin systems using chemical shift rules and the sets are ordered using sequential 3D connectivities. By matching long stretches of such sequentially linked spin systems versus

Figure 10 Sequential walk through f_1 - f_2 planes in the NH region of the 3D NOESY-TOCSY spectrum of parvalbumin for f_3 frequencies of NH(Asp92) to NH(Ile97), taken from Vuister et al.⁸ The spin system is indicated by vertical lines for each plane. The NOEs with the C- α atom can be found on the horizontal line parallel to the NOE line at the C- α resonance frequency. A back-transfer peak, $C_{N\alpha N}(i, i, i)$, is found at the crossing with the vertical NH line. The other cross peaks on this horizontal line in the NH region represent potential sequential cross peaks $C_{N\alpha N}(i + 1, i, i)$. The vertical line connecting to the next f_1 - f_2 plane defines the NH frequency of the neighboring residue. The number of choices for sequential connectivities is significantly reduced compared with that observed in 2D spectra. Note that at Gly95 the sequential $C_{N\alpha N}(i + 1, i, i)$ connectivity is lacking, but that in this case use has been made of the single-step d_{NN} connectivity on the NOE line. (Reproduced by permission from Vuister et al.⁸)

Table 1 Sequential Connectivities in 2D and 3D NMR^a

	α -helix	β -sheet
2D NOE or NOE plane		
$d_{\alpha N}$	w	s
d_{NN}	m	a
3D NOESY–TOCSY		
$d_{\alpha N} C_{N\alpha N}(i + 1, i, i)$	a–w	s
$C_{\alpha N\alpha}(i - 1, i, i)$	a–w	s
$d_{NN} C_{NN\alpha}(i + 1, i, i)$	m	a–w
$C_{NN\alpha}(i - 1, i, i)$	m	a–w

^aCross peak intensities: s, strong; m, medium; w, weak or a, absent. The estimates for the intensities in the 2D NOE spectra are taken from Wüthrich,¹ those for the 3D NOESY–TOCSY spectra are calculated as described by Vuister et al.⁶⁶

the amino acid sequence it is possible to assign almost all residues of parvalbumin.⁵⁴

In a semiautomatic procedure the analysis of 3D spectra can take place in f_1 – f_2 , f_2 – f_3 , or f_1 – f_3 planes: the relationships among the cross peaks in different planes are established by the rules within the program. In an interactive analysis, especially on paper, patterns are more easily recognized in a single plot. The analysis of 3D TOCSY–NOESY and 3D NOESY–TOCSY spectra in f_1 – f_3 planes has been found to be convenient, since the pattern of HOHAHA related cross peaks and the NOE relationship of this pattern with other resonances can be observed in one plane. Such planes are useful for identifying amino acid spin systems and a sequential assignment strategy mainly using f_1 – f_3 planes has been outlined.^{42,65}

Of course, it is not necessary to use just one 3D TOCSY–NOESY spectrum for assigning the resonances. A pragmatic approach uses 2D TOCSY and NOESY spectra for identifying the interactions between nonoverlapping resonances, whereas ambiguities are sorted out using the 3D spectra. Such procedures have been used for neocarzinostatin,⁶⁹ leghemoglobin,⁷² procolipase,⁷³ the DNA binding domains of LexA repressor,⁷⁴ and the transcription elongation factor TFIIS.⁷⁵ Also for interleukin-4²¹ and for azurin,⁷¹ 3D TOCSY–NOESY and 3D NOESY–(¹⁵N, ¹H)–HMQC were used together to resolve ambiguities in the assignments.

8.4 Identification of Spin Systems using 3D TOCSY–TOCSY Spectroscopy

An essential step for the sequential analysis of protein NMR spectra is the identification of spin systems. It has been demonstrated that 3D TOCSY–TOCSY spectroscopy can be of great help for deciphering spin systems.⁷⁶ The analysis of a 3D TOCSY–TOCSY spectrum is more straightforward than that of a 3D TOCSY–NOESY spectrum, since each 3D cross peak already defines three frequencies of the spin system. Similarly as in 3D TOCSY–NOESY spectra, it is relatively easy to recognize in the f_1 – f_3 planes the 3D cross peaks belonging to one spin system, even in the case of overlap at the f_2 frequency. Oschkinat et al.⁵⁸ have proposed a strategy for automated assignment of proteins, where the spin systems would be identified using a 3D TOCSY–TOCSY spectrum and the sequential connectivities between the spin

systems are obtained from a 3D TOCSY–NOESY spectrum. 3D TOCSY–TOCSY spectra can be very useful in those cases where strong overlap prohibits the analysis of spin systems but where efficient HOHAHA transfer is still present.

8.5 Analysis of 3D NOESY–NOESY Spectra

For larger proteins it becomes more difficult to establish the proton–proton J coupling via COSY and HOHAHA transfer steps. A 3D technique, where both mixing periods are due to cross relaxation, is in principle not limited by molecular weight. Suitable mixing periods are NOE or ROE. Thus, 3D NOESY–NOESY spectroscopy was proposed, where a NOE is now relayed by NOE to another nucleus.¹¹ However, since the relay can be to any neighboring nucleus, the analysis of 3D NOESY–NOESY spectra can be complex. Furthermore, since in general the NOE is weak and the relay can be to several other nuclei, a relatively low sensitivity for the 3D NOESY–NOESY could be expected. Nevertheless, 3D NOESY–NOESY spectra of good quality have been presented.^{41,77–79} For proteins it has been demonstrated that the amide protons show connectivity patterns very similar to 3D NOESY–TOCSY spectra.⁷⁷ A statistical analysis of expected connectivities in 3D NOESY–NOESY spectra for 28 crystal protein structures shows that patterns of highly correlated cross peaks exist, suggesting that assignments for proteins could be based largely on NOE data.⁸⁰ A very complete analysis of sequential and medium range connectivities has been made for the 3D NOESY–NOESY spectrum of parvalbumin.^{41,78} For the 109-residue parvalbumin the HOHAHA transfer is generally more efficient than the NOE transfer, thus the number of sequential and medium range connectivities in the 3D NOESY–NOESY spectrum is slightly less than that of a 3D TOCSY–NOESY spectrum. For proteins with a less efficient HOHAHA transfer, however, 3D NOESY–NOESY may perform better.

8.6 Structural Studies of Proteins

Stretches of sequential and medium range 3D connectivities can be used as indicators for α -helical, β -sheet, or turn-like structures. Thus, for the proteins parvalbumin⁶⁸ and aponeocarzinostatin⁶⁹ it was demonstrated that most of the secondary structure assignments found in 2D NOE spectra can be obtained from a 3D TOCSY–NOESY spectrum, but with fewer ambiguities. The secondary structures of a phospholipid transfer protein⁷⁰ and of leghemoglobin⁷² are based on a combination of homonuclear 2D and 3D data. For ferrocycytochrome *c*₅₅₃ several crucial long range NOEs could be established from 3D TOCSY–NOESY spectra.⁸¹ Similarly, many NOE restraints used for the structure determinations of procolipase⁷³ and the DNA binding domain of LexA repressor⁷⁴ were obtained with help from 3D TOCSY–NOESY data.

Long-range NOEs can also be observed by 3D NOESY–NOESY. Thus, 3D NOESY–NOESY data resolved crucial long range connectivities for the structure determination of the DNA binding domain of LexA repressor.⁷⁴ The analysis of 3D NOESY–NOESY spectra is complex, since a large number of cross peaks can be expected and the magnetization transfer is not limited to spin systems. The analysis improves by

comparing patterns of 3D cross peaks. For example, if for spin B a characteristic pattern of cross peaks $\{(A, B, P), (A, B, Q), \text{ and } (A, B, R)\}$ has been observed, the 3D NOESY–NOESY spectrum can be searched systematically for the patterns $\{(C, B, P), (C, B, Q), \text{ and } (C, B, R)\}$ and $\{(P, B, C), (Q, B, C), \text{ and } (R, B, C)\}$. If the pattern at the row defined by $(f_1, f_2) = (A, B)$ was observed virtually without overlap, this search is effectively a convolution of the 3D spectrum with this row. Visually, this pattern can be easily recognized in an f_1 – f_3 plane. Next, one has to analyze the pattern at $(f_1, f_2) = (B, C)$ in order to establish the nature of nucleus C. In this way the pattern of relayed intensities, which was unfavorable for an optimal signal-to-noise ratio of the 3D spectrum, turns out to be beneficial for pattern recognition. Once the 3D cross peaks have all been assigned, the intensities of the 3D cross peaks can be converted into constraints for structure refinement.

8.7 Distance Constraints from 3D Data

For structure refinement it is important to obtain as many distance constraints as possible.¹ For this, 3D spectra can be very useful, since they may resolve many ambiguities in the spectral interpretation of NOE data, and therefore lead to more restraints.⁸² It is, however, also possible to use the 3D spectra directly for obtaining distance constraints. The 3D cross-peak intensity is proportional to the product of the two transfer efficiencies of the two mixing periods of a 3D experiment:

$$I_{ijk} \propto T_{ij}T_{jk} \quad (1)$$

Several approaches have been described for interpreting the 3D intensity. The ratio of the intensity of the cross peak C(A,B,C) of a 3D TOCSY–NOESY, or a 3D NOESY–NOESY spectrum and the intensity of the cross-diagonal cross peak C(A,B,B) defines the transfer efficiency T_{bc} :

$$I\{C(A,B,C)\}/I\{C(A,B,B)\} = T_{bc}/(1 - T_{bc}) \quad (2)$$

From this NOE transfer efficiency, T_{bc} distances can be obtained in a similar way as from regular 2D data. The relationship between NOE transfer efficiency and cross relaxation rates is

$$\mathbf{T} = \exp(-\tau_m \mathbf{R}) \quad (3)$$

where $\mathbf{T}$ and $\mathbf{R}$ are the NOE transfer and cross-relaxation matrices, respectively, and τ_m the NOE mixing period. Generally, transfer efficiencies are compared with those of protons at known distances and the approximate relationship

$$T_{bc}/T_{de} = (r_{de}/r_{bc})^6 \quad (4)$$

is used. In the case of overlap at the cross-diagonal planes it is still possible to obtain the ratio of the cross peaks C(A,B,C) and C(A,B,F) which defines the ratio T_{bc}/T_{bf} and thus the ratio of the distances r_{bc}/r_{bf} .⁸³ If the distance r_{bf} is known, the distance r_{bc} can be derived.

A more quantitative approach uses the cross-peak intensities of a 3D NOESY–NOESY spectrum. The relationship between NOE and distance is only an approximate one, due to spin

diffusion at longer NOE mixing times. Approximating this multiple-step NOE transfer to second order, the NOE intensity is equal to

$$T_{ij} = -R_{ij}\tau_m + \sum R_{ik}R_{kj}\tau_m^2 \dots \quad (5)$$

The second term in equation (5) describes spin diffusion via other spins. The intensity of a cross peak in a 3D NOESY–NOESY spectrum is to a first approximation equal to

$$T_{ikj} = R_{ik}R_{kj}\tau_m^2 \dots \quad (6)$$

Thus the cross peaks in a 3D NOESY–NOESY spectrum define the contributions of the several spin diffusion paths via other nuclei.¹¹ Therefore the 3D NOESY–NOESY intensities can be used to obtain more accurate cross-relaxation rates between proton pairs, as has been shown by Kessler et al.⁸⁴ and Habazettl et al.⁸⁵

The 3D NOESY–NOESY intensities can also be used as direct constraints for a structure refinement. This requires the calculation of the gradients of the 3D intensities with respect to the coordinates of the protons in a molecule. The gradient of a 3D NOESY–NOESY peak with a net transfer T_{ijk} can be written⁸⁶ as the sum of two terms containing the separate gradients of T_{ij} and T_{jk} :

$$\nabla T_{ijk} = T_{ij}\nabla T_{jk} + \nabla T_{ij}T_{jk} \quad (7)$$

The transfer efficiencies T_{ij} and T_{jk} can be obtained from relaxation matrix methods (cf. Bonvin et al.⁸⁷), while the derivatives of the 2D efficiencies can be solved exactly⁸⁸ or be approximated.⁸⁹ equation (7) has been used to obtain 3D NOE restraining potentials for use in restrained molecular dynamics calculations.^{86,90,91}

$$V_{3DNOE} \sim \sum_{ijk} (T_{ijk} - T_{ijk}^{obs})^2 \quad (8)$$

where T_{ijk} and T_{ijk}^{obs} are the calculated and observed transfer efficiencies, respectively. The minimization of the 3D NOE potential requires the calculation of ∇V_{3DNOE} . This can be accomplished by combining equations (7) and (8) as

$$\nabla V_{3DNOE} \sim \sum_{ijk} 2(T_{ijk} - T_{ijk}^{obs})(T_{ij} \cdot \nabla T_{jk} + \nabla T_{ij} \cdot T_{jk}) \quad (9)$$

It has been shown that the use of the 3D cross-peak intensities can lead to a better definition of the structures of proteins than the use of only 2D NOE data.

8.8 Protein Hydration Studies

Cross peaks in a NOESY spectrum at a line corresponding to the f_1 frequency of water can identify protons with a close proximity to water.⁹² The overlap of proton signals on this line can be removed by transferring the magnetization in a second magnetization transfer step to a third nucleus. Thus, Otting et al.⁹³ have demonstrated the use of 3D NOESY–TOCSY and 3D ROESY–TOCSY for studies of protein hydration,

whereas Holak et al.⁹⁴ have used 3D NOESY–NOESY. In contrast to 2D methods, where the NOEs with water protons are all observed on a single frequency axis, the f_2 – f_3 planes of 3D spectra at the f_1 frequency of water reveal the protons interacting with water via cross peaks in a two-dimensional map. This reduces overlap and helps to assign the protons involved. The comparison of the sign and intensities of the cross peaks in the f_2 – f_3 planes of the 3D NOESY–TOCSY and 3D ROESY–TOCSY spectra distinguishes NOE and exchange effects.

8.9 Homonuclear 3D NMR of Oligosaccharides

The small chemical shift dispersion of the sugar-skeleton protons of oligosaccharides poses a major problem for structural studies. It is often still possible to obtain assignments on the basis of 2D HOHAHA experiments by exploiting the chemical shift dispersion of the anomeric protons. However, the unique identification of NOEs involving protons in the bulk region between 3 and 4 ppm is very difficult. The resolution in the bulk region can be increased by the application of 3D NOESY–TOCSY techniques, which relay the magnetization from the bulk protons to the anomeric signals.^{83,95}

An example is given in Figure 11, which shows the f_1 – f_2 plane at the f_3 frequency of the Man-4 H-2 anomeric signal of a biantennary asparagine-linked oligosaccharide at 4.19 ppm. An interesting 3D cross peak is observed at the f_1 frequency of Man-3 H-2, which shows the presence of an NOE between Man-4 H-5 and Man-3 H-2. The existence of this NOE was the subject of considerable discussion in the literature, although it

was settled later by deuteration studies (see Vuister et al.⁹⁵ for a discussion). This NOE effect is found directly in the 3D NOESY–TOCSY spectrum.

8.10 Homonuclear 3D NMR of DNA and RNA Fragments

For the sequential assignment of DNA and RNA fragments it is necessary to correlate the NOEs of the aromatic protons of the nucleic acid bases with their own sugar protons and those of their neighbor. 3D TOCSY–NOESY spectra can be used for this purpose.^{96,97} It turns out that even the very crowded 4',5',5'' region of DNA fragments now becomes accessible for analysis. Thus, 3D TOCSY–NOESY was used for a 15-residue DNA hairpin,⁹⁶ and 3D NOESY–TOCSY for a 31-residue pyrimidine–purine–pyrimidine DNA triplex.⁹⁷ Homonuclear 3D methods are very useful for RNA fragments, where considerable overlap exists for most sugar protons. Thus, most proton assignments can be obtained from a single 3D TOCSY–NOESY spectrum, as demonstrated for a 12-mer RNA duplex.⁹⁸

Structural studies of DNA fragments can use 3D NOESY–TOCSY methods for resolving ambiguities in the assignment of cross peaks in 2D NOE spectra. Such methods have been applied for the analysis of the NOEs of a 12-mer DNA duplex containing a GG mismatch⁹⁹ and for analysis of a modified 12-mer DNA duplex.¹⁰⁰ In both cases the 3D spectra clarified unusual NOEs, with important consequences for the geometry.

For larger DNA and RNA fragments the HOHAHA transfer could turn out to be inefficient. In this situation 3D NOESY–NOESY is an alternative, since it is not based on a possibly weak homonuclear J coupling, and cross relaxation becomes increasingly efficient at higher molecular weights. It has been demonstrated that 3D NOESY–NOESY spectra of good quality can be recorded for a 22-mer duplex.¹¹ Similarly, 3D NOESY–NOESY has been applied to a 40-base three-stranded DNA junction,¹⁰¹ where it allowed the completion of the proton assignments and confirmed the unusual geometry at the junction, and to a hybrid DNA–RNA dodecamer duplex,¹⁰² where it resolved superimposed cross peaks of the RNA strand.

9 PROSPECTS FOR 3D NMR SPECTROSCOPY

The NOE effect and the J coupling can be combined in three different ways in homonuclear 3D NMR experiments. 3D experiments with a simple magnetization transfer such as in 3D COSY–COSY are most amenable for analysis. However, the linewidth of larger biomolecules is of a similar magnitude to the $^3J(\text{H}, \text{H})$ coupling, which leads to weak 3D cross-peak intensities. Magnetization transfer by HOHAHA is less sensitive to line broadening, and is therefore preferable for most applications. Thus, spin systems of biomolecules with molecular masses below 20 kDa can be analyzed using 3D TOCSY–TOCSY and 3D NOESY–TOCSY spectra. Furthermore, these latter spectra turn out to be useful in assigning resonances and analyzing the secondary and even the tertiary structure of proteins. For biomolecules of greater mass than 20 kDa or with a large linewidth, mixing periods based on $J(\text{H}, \text{H})$ couplings may not be efficient. In this case 3D NOESY–NOESY or 3D ROESY–ROESY experiments can

Figure 11 f_1 – f_2 plane of the 3D NOESY–TOCSY spectrum of 20 mM biantennary oligosaccharide in D_2O at 304 K and pH = 7. The cross section shown is at the f_3 resonance position of Man-4 H-2 (4.19 ppm). The $144 \times 144 \times 1024$ data set was recorded at 500 MHz in 63 h using eight scans. The NOE mixing time was 350 ms and the HOHAHA mixing time 94 ms. The spectrum was processed to a resolution of $256 \times 256 \times 512$. (Adapted by permission from Vuister et al.⁹⁵)

be used for resolving the overlap of cross peaks in NOESY and ROESY spectra.

The analysis of many multidimensional NMR spectra may benefit from the development of programs which allow the graphical and interactive bookkeeping of the spectra on workstations. This is particularly true for the homonuclear 3D spectra of biomolecules, where the large number of interactions and the fact that the relay is to many other nuclei often leads to many cross peaks. Since the analysis of such spectra can be complex, a practical approach where the 3D spectra assist the analysis of 2D TOCSY and NOESY spectra seems to be the most fruitful. A further improvement for all multidimensional techniques is the application of field gradient methods using shielded gradient coils. This may allow a reduction in the phase cycling for coherence selection and artifact suppression, so that spectra can be obtained with a significant higher resolution per domain. This is particularly important for the automated analysis of multidimensional spectra, where a large tolerance in the coordinates of a cross peak due to low resolution may result in a large number of possible assignments.

Another class of 3D NMR experiments, not discussed in detail in the present overview, is formed by the heteronuclear 3D NMR experiments, such as 3D TOCSY-HMQC and 3D NOESY-HMQC. These methods also use a third dimension to increase the resolution. Compared with the homonuclear proton methods they have the advantage of an efficient J transfer due to the large ^{15}N - ^1H and ^{13}C - ^1H coupling constants. For sufficient sensitivity, it is generally necessary to obtain isotopically enriched biological material. For doubly (^{13}C , ^{15}N) labeled proteins and ^{13}C labeled oligonucleotides straightforward and powerful methods have been developed both for assigning resonances and for structural studies (see Clore and Gronenborn¹⁹ and Oschkinat et al.²¹ for reviews). In many cases, however, labeling may be impossible to realize, and then homonuclear 3D methods are still possible. In other cases only ^{15}N labeling may be feasible. It is then possible to record 3D TOCSY-NOESY- $(^{15}\text{N}, ^1\text{H})$ -HSQC spectra^{103,104} or 4D TOCSY-NOESY- $(^{15}\text{N}, ^1\text{H})$ -HSQC spectra¹⁰⁵ to resolve ambiguities in 3D NOESY- $(^{15}\text{N}, ^1\text{H})$ -HSQC spectra. It turns out that the analysis of such spectra is very similar to that of the homonuclear 3D TOCSY-NOESY spectra.

During the past few years many homonuclear and heteronuclear 3D NMR experiments have been developed. These methods can complement each other and should be explored to their limits for studying larger and more complex biomolecular systems.

1 INTRODUCTION

Plasma lipoproteins are multimolecular complexes composed of varying proportions of protein, phospholipid, cholesterol, cholesteryl ester, and triglyceride.¹ The three major classes of plasma lipoproteins are the very low density lipoproteins (VLDL), low density lipoproteins (LDL), and high density lipoproteins (HDL). The VLDL transport endogenously synthesized triglyceride from the liver to peripheral tissues, where they undergo lipolysis to provide free fatty acids (FFA) required for energy metabolism, and membrane biosynthesis. Progressive lipolysis of VLDL triglycerides produces a cascade of remnant particles ultimately leading to the formation of LDL. LDL particles, although poor in triglyceride, are rich in cholesteryl ester, which is delivered to various peripheral cells by predominantly receptor mediated uptake. Plasma concentrations of LDL are directly correlated with coronary artery disease. HDL are relatively protein rich lipoproteins that take up excess cholesterol from the surface of peripheral cells and transport it to the liver where it is either reutilized or catabolized and excreted. The plasma concentration of HDL is inversely correlated with coronary artery disease. Other normally less abundant lipoproteins such as chylomicrons, Lp[a], β -VLDL, and IDL represent variants of the above described major classes. The central role played by lipoproteins in lipid metabolism and several disease states have elicited their intensive study by many investigators using numerous techniques. NMR has been especially effective in elucidating the structure and monitoring the metabolism of lipoproteins because they contain an abundance of naturally occurring, magnetically active nuclei (^3P , ^1H , and ^{13}C), and because of the sensitivity of NMR to the diverse chemical and physical environments in which these nuclei occur.

Since the last comprehensive review on NMR of lipoproteins,² technical advances have included higher field magnets,

faster computational hardware, and improved data processing software. These developments have made possible increasingly sophisticated applications of NMR to the study of lipoproteins, not only in their purified form but also in whole plasma, resulting in intensive interest in the use of NMR spectroscopy for medical diagnosis. This article provides a concise summary of some of these more recent applications, as well as a survey of NMR studies of native, modified, and model lipoproteins.

2 ISOLATED NATIVE LIPOPROTEINS

Phosphorus-31 NMR spectra of plasma lipoproteins are quite simple, since the ^{31}P nucleus is present almost exclusively in the phosphate group of phospholipids. The first reported ^{31}P spectra of HDL showed two narrow resonances which quantitatively reflected the major phospholipid species of HDL, phosphatidylcholine (PC) and sphingomyelin.^{3,4} Their chemical shifts are consistent with location of the phospholipid polar groups at the aqueous interface; the narrow lines indicate that the phosphate groups have homogeneous environments and rapid molecular motions. Quantification of the intensity of the ^{31}P NMR resonances of LDL suggests that a small fraction of phospholipids interact with the protein (apoB-100), similar to the interaction of boundary membrane lipids with membrane proteins.⁵ The effects of several paramagnetic reagents on the ^{31}P resonances in spectra of HDL and LDL have been studied. Although all studies showed at least 50% diminution of the intensity of these resonances by paramagnetic reagents, consistent with the phosphoryl groups being at the aqueous interface, different reagents had quantitatively different effects.^{4,6,7} Use of the paramagnetic ion Pr^{3+} demonstrated a phospholipid bilayer structure in the abnormal lipoprotein LP-X, which is present in the plasma of patients with obstructive liver disease and lecithin-cholesterol acyltransferase deficiency.⁸ Lateral diffusion of phospholipids in various lipoproteins has been estimated from the viscosity dependence of ^{31}P linewidths; LDL phospholipids exhibit a large increase in diffusion rate over the temperature range of the phase transition of cholesteryl esters in the hydrophobic core.⁹ The phospholipids of lipoproteins can be quantified accurately according to headgroup species by detergent solubilization.¹⁰ An interesting application to lipoprotein metabolism is the use of ^{31}P NMR to monitor phospholipase A_2 hydrolysis of HDLs.¹¹ The time-dependent intensity changes for resonances reflecting PC and lyso-PC accurately describe the reaction rate, and the constancy of the linewidths suggests that there are no major changes in the interfacial structure. In general, ^{31}P NMR has seen limited application in studies of lipoprotein structure and dynamics since the spectra provide information about only one region of one lipid type present in lipoproteins.

The use of ^{13}C NMR spectroscopy to study plasma lipoproteins was not feasible before the development of Fourier transform NMR and large probes accommodating 15 and 20 mm sample tubes in order to overcome the inherently low sensitivity and abundance of the ^{13}C nucleus. The main advantage of ^{13}C , compared with ^1H , NMR for the study of lipoproteins was demonstrated in the earliest published spectra;^{12,13} ^{13}C spectra even at low field (1.4 T, Figure 1) are better resolved and contain more accessible information than ^1H spectra at much higher field. Improved resolution,

Figure 1 Natural abundance ^{13}C Fourier transform NMR spectra (15.2 MHz) of human plasma lipoproteins at 36 °C recorded with ^1H decoupling in 20 mm sample tubes. Conditions: 250 ppm spectral width, 4096 time domain points, 0.555 s recycle time. The insets were printed with a $4 \times$ vertical expansion. Digital broadening of 0.3 Hz (full spectra) and 2.4 Hz (insets) was used to improve the signal-to-noise ratio. Peak numbers are the same as those shown in parentheses in Table 1. (a) VLDL, 37 mg mL $^{-1}$, pH 7.5 after 165 254 accumulations (25 h); (b) LDL, 110 mg mL $^{-1}$, pH 7.5, after 65 536 accumulations (10 h); (c) HDL, 70 mg mL $^{-1}$, pH 8.6, after 65 536 accumulations (10 h). CH ₃ –CH ₂ –	14.1 (27)	14.1 (25)	14.1 (28)
Cholesterol C-18	12.0 (28)	11.9 (26)	12.0 (29)

^aChemical shifts are in ppm with increasing frequency from tetramethylsilane. The terminal methyl group of fatty acyl chains at 14.1 ppm was used as an internal reference. Numbers in parentheses after chemical shifts are the peak designations in the spectra of VLDL [see Figure 1(a)], LDL [see Figure 1(b)], and HDL [see Figure 1(c)]. Unless otherwise noted, the assignments refer to the fatty acyl chain. *C* indicates the specifically assigned type of carbon. Chemical shifts accurate to ± 0.2 ppm (Hamilton et al.13).

^bShoulders down frequency from peak 5 in Figure 1(c).

^cCould not be identified unambiguously.

^dMay also contain ϵ -carbon of lysine and β -carbon of leucine in HDL spectrum.

^eShoulder in Figure 1.

^fBarely discernible at about 28 ppm.

together with the absence of spin couplings, make assignments (Table 1) easier and more reliable. Peaks representing the major lipids of each lipoprotein class were detected (Table 1). The ^{13}C spectra of HDL and LDL (Figure 1) showed greater differences than the corresponding ^1H spectra.² Notably, minor contributions of protein signals were seen in the spectrum of HDL. Comparative HDL studies at 1.4,¹³ 4.7,¹⁴ and 9.4¹⁵ T show a significant difference in resolution between spectra acquired at the two lower fields, and a more modest difference at the two higher fields. In ^{13}C NMR spectra at >4.7 T, at least one well resolved single carbon resonance for each lipid type is observed. Higher magnetic fields and instrument improvements have led to greatly increased sensitivity so that large sample volumes and extremely long accumulation times

are no longer required to obtain high quality ^{13}C spectra of lipoproteins.

Carbon-13 NMR studies have led to a more detailed description of the molecular motions, structure, and organization of the lipids in lipoproteins than perhaps any other single technique. The narrow widths of lipid resonances that dominate the spectrum, together with the measured spin–lattice relaxation times (T_1), indicate a liquid-like state for most lipoprotein lipids.^{12,13} Generally, resonances of corresponding carbons on different acyl chains within the same lipid molecule (e.g. PC and triglyceride) are not distinguishable by chemical shift; hence T_1 (as well as linewidth and NOE) measurements represent an average of potentially different values. However, ^{13}C NMR is fully capable of distinguishing between esterified and

unesterified cholesterol because of significant differences in the chemical shift for C-3, C-4, C-5, and C-6 steroid ring carbons. The resolved cholesteryl ester C-6 resonance can be used as a probe of steroid ring motions; T_1 , linewidth, and NOE values for this carbon show that steroid ring motions are in the nanosecond range, indicative of a viscous environment for this lipid type in lipoproteins.^{12,13} In the spectrum of HDL, the observed narrow cholesterol resonances (C-5 and C-6) represent only about one-third of the total cholesterol; this pool of cholesterol is considered most likely to be in the liquid core.^{14–16} The second, more motionally restricted pool of cholesterol was suggested to be in the surface based on studies using exogenously added cholesterol enriched at C-4.¹⁷

Carbon-13 NMR spectroscopy has helped to define the emulsion structure of lipoproteins, particularly the structural organization of the neutral lipid core. Observation of single carbon signals from the steroid ring of cholesteryl esters has permitted direct detection of the cholesteryl ester phase transition in LDL.¹⁸ ^{13}C NMR has shown that the transition reflects a liquid phase to ordered phase change; however, this ordered phase does not closely resemble the smectic phase of isolated cholesteryl esters, as suggested by X-ray diffraction studies. Carbon-13 resonances from phospholipid carbons located at the aqueous interface (i.e. choline and carbonyl carbons) are only slightly affected by temperature changes, indicating an essentially separate uncoupled 'core' phase. An important extension of the above investigation was the detection of lipid signals in intact (excised) human arterial tissue containing atherosclerotic plaques.¹⁸ Spectra of plaques reflected lipid deposits rather than membrane constituents, and a liquid-ordered phase transition of cholesteryl esters was observed below body temperature. The spectra of plaque had a striking overall resemblance to the spectra of thermally disrupted LDLs. A similar approach was used to correlate the structural organization of cholesteryl esters in rabbit lipoproteins and aortic atherosclerotic lesions.¹⁹ Temperature dependent ^{13}C spectra revealed a cholesteryl ester phase transition above physiological temperature in lesions and in lipoproteins (LDLs and cholesteryl ester-rich VLDL) from these cholesterol-fed rabbits. The cholesteryl ester phase transitions in cholesteryl ester-rich VLDL from cholesterol-fed rabbits was studied in detail by ^{13}C NMR.²⁰ Accompanying data from spin labeled cholesteryl esters and phospholipids showed that neither of these spin-labeled lipids detected the core transition, but the acyl chain order of phospholipids was greater in cholesteryl ester-rich VLDL than in normal VLDL. The structural organization and molecular motions of cholesteryl esters in HDL have also been studied in detail.¹⁴ Temperature dependent spectra showed no evidence of a core transition, and the molecular motions of cholesteryl esters were well modeled by a cholesteryl ester-triglyceride mixture.

As with other types of NMR, ^{13}C NMR has limitations in applications to lipoproteins. Some of these limitations are the inability to detect minor components or to discriminate resonances arising from corresponding carbons on different acyl chains, problems that can be overcome by ^{13}C enrichment (see below). ^{13}C NMR spectra of native lipoproteins reveal very little about the protein moieties, primarily because of the much greater linewidths of most of the protein signals and much higher molar concentration of lipids.^{12,13} Consequently, few details of lipid-protein interactions in lipoproteins have been elucidated by ^{13}C NMR to date, except in the case of

albumin reconstituted with ^{13}C -enriched fatty acids and a few model lipoprotein systems described below.

The first application of NMR spectroscopy to lipoproteins utilized ^1H NMR, because of the high NMR sensitivity, abundance, and wide distribution of protons. Considering the vast number of chemically different protons in the lipids and proteins of plasma lipoproteins, the ^1H spectra are remarkably simple. The first published spectra (at 60 MHz) showed very few peaks, and these were attributed to the lipid components based on comparison of spectra of intact lipoproteins with those of sonically dispersed lipids.²¹ Early ^1H spectra at a higher field (220 MHz) showed additional resonances, some of which were thought to represent protein but which could not be unambiguously assigned.²² More recently, all resonances of ^1H spectra of lipoproteins have been attributed to lipids,² consistent with heteronuclear (^{13}C , ^1H) 2D NMR spectral assignments.²³

In practice, the large amount of information contained in the ^1H spectrum is of limited accessibility. The poor resolution of ^1H NMR lipoprotein spectra complicates not only assignments but interpretation of linewidth and spin-lattice relaxation data. Except for lipoproteins that contain a predominance of one lipid type (e.g. chylomicrons and VLDL containing triglyceride; LP-X containing unesterified cholesterol), ^1H spectra consist mainly of overlapping resonances for different lipid types. The splitting of peaks by scalar coupling also makes quantitative interpretation of ^1H linewidths difficult; splittings are observed clearly only in the narrow triglyceride resonances of chylomicrons and VLDL, and are obscured by line broadening in spectra of LDL and HDL. Interpretation of ^1H T_1 values is complicated by the contribution of both intra- and intermolecular contributions to ^1H relaxation processes.²⁴

In spite of inherent limitations, ^1H NMR spectroscopy has helped to define general features of the structural organization of plasma lipoproteins. The earliest studies suggested that lipid-lipid interactions were dominant and that most of the lipids were in a liquid state.²¹ The sensitivity of the choline methyl resonance to shift reagents has been used to demonstrate that this moiety is present at the aqueous interface.^{25,26} In LDL and HDL, the existence of a hydrophobic core which can undergo thermal changes was shown by temperature dependent peak intensity changes. In LDL, a discrete phase transition can be attributed to a liquid to ordered phase change of cholesteryl esters by comparison with spectral changes of pure cholesteryl esters, although specific resonances for cholesteryl esters are not seen in the ^1H spectrum of intact LDL.²⁴ Spectra of VLDL and chylomicrons are dominated by the constituent triglycerides, and the liquid to solid phase transition of triglycerides can be monitored readily.^{27,28}

^1H is the most sensitive NMR nucleus (except for ^3H), giving ^1H NMR spectroscopy an important versatility. Numerous spectra can be acquired as a function of a given variable, and high quality spectra can be obtained in a short time with <1 mg lipid mL^{-1} . The higher sensitivity of ^1H NMR has led to its application in studies of whole plasma (see below).

3 LIPOPROTEINS IN PLASMA

Proton spectra of plasma reflect its multiple lipid components with different molecular structures and mobilities. Quantitative

Figure 2 Results of methyl resonance lineshape analysis of ^1H spectra obtained at 23 and 40°C for a simulated plasma sample of known lipoprotein composition (left) and an authentic plasma sample (right). Beneath the experimental (solid line) and calculated (dashed line) plasma spectra are shown the derived amplitudes of the four component spectra used for the fit. The 23°C spectra are plotted with 50% increased vertical scaling compared with the 40°C spectra. The authentic plasma sample contained 1.85 g (2.09 mmol) of triglyceride, 0.42 g (1.09 mmol) of HDL cholesterol, and 1.31 g (3.39 mmol) of LDL cholesterol per liter. (Reproduced by permission of American Association of Clinical Chemists from Otvos et al.²⁹)

measurements of linewidths and intensities are also complicated by extensive resonance overlap and temperature dependent spectral effects. The lower frequency (0–2.0 ppm) region of the ^1H spectrum of plasma is dominated by lipoprotein lipids which give rise to envelopes of methylene (~ 1.2 ppm) and methyl (~ 0.8 ppm) resonances. Because of the small but significant differences in the average chemical shifts for the CH_2 and CH_3 envelopes in the different lipoprotein classes,²⁹ the shapes of these envelopes in the plasma spectrum are controlled by the relative abundance of the different lipoprotein classes. Otvos et al.²⁹ have developed a method for quantifying the concentrations of chylomicrons, VLDL, LDL, and HDL in whole plasma based on spectral deconvolution of the CH_3 envelope (Figure 2). The effects of temperature (15–45°C) on lineshapes and intensities were analyzed quantitatively. The rapid, accurate measurement of these lipoprotein classes has immediate application for the diagnosis of specific types of hyperlipoproteinemia such as hyperchylomicronemia (type 1), hypercholesterolemia (type 2), and hyper- α -lipoproteinemia.

Analysis of the methylene envelope (~ 1.2 ppm) may sometimes be compromised by the presence of other nonlipid species such as ethanol (1.2 ppm), lactate (1.34 ppm), and β -hydroxybutyrate (1.21 ppm).³⁰ Experimental conditions which might affect the lineshape, chemical shift, or amplitude of these

two spectral envelopes include sample storage temperature and spectral acquisition conditions (water suppression technique, sample temperature, and magnetic field inhomogeneity).³¹

Fossel and associates,³² using the average width of the methyl and methylene resonances of proton spectra, measured values for plasma from normal control subjects (39.5 ± 1.6 Hz) that were significantly greater than those for patients with untreated cancer (29.9 ± 2.5 Hz). This study led to the conclusion that proton NMR spectroscopy of plasma is potentially valuable for the detection of cancer and monitoring its therapy. The possibility of using a noninvasive method to detect cancer attracted much attention to NMR spectroscopy in general, and to spectroscopy of lipoproteins in particular. However, it was soon pointed out that there are several important caveats and significant limitations to using this method for cancer detection.³³ Dietary variations as well as numerous abnormal nonmalignant conditions can lead to alterations in the amounts and composition of different lipoproteins, which, as indicated above, make different contributions to the composite shape of the CH_2 and CH_3 envelopes. For example, nonfasted subjects or those with fasting hypertriglyceridemia can be expected to have elevated levels of triglyceride-rich lipoproteins whose acyl chains have high segmental flexibility and relatively narrow

spectral lines.^{27,28} Indeed, individuals with triglyceride levels above 110 mg dL⁻¹ will have average CH₂ and CH₃ resonance linewidths that may be interpreted erroneously to indicate cancer if the suggested threshold of 33 Hz is used.³⁴ Since fasting plasma triglyceride levels of less than 190 mg dL⁻¹ are generally considered normal, such positive results could represent a substantial proportion of normal healthy subjects. A number of studies have been performed to determine the value of the ¹H NMR spectrum of plasma for the accurate diagnosis of metastatic disease.^{35–39} Some of these studies have found a significant difference between the means of the average linewidths of normal subjects and untreated cancer patients. However, most of the reported studies have also found considerable overlap in the groups classified with or without disease. The extent of this overlap has been the center of considerable controversy since the original report by Fossel et al.³² In a typical study, the degree of overlap corresponded to 74% sensitivity and 59% specificity, results which do not allow use of this methodology to diagnose malignant disease accurately.³¹

Proton NMR spectroscopy has also been evaluated for its utility in diagnosing other disease states or metabolic conditions. The methyl and methylene linewidths alone, as well as their average, are strongly inversely correlated with triglyceride-rich lipoprotein levels in both the fasting and postprandial states.^{40,41} In a study of subjects with liver disease (hepatocarcinoma or liver cirrhosis), the average linewidth of the methyl envelope (41.3 Hz) was significantly different from that of normal controls (29.6 Hz); however, the methylene envelope did not have this diagnostic potential.⁴² In a study of more than 400 plasma samples from 46 patients who had undergone heart transplantation, the methyl/methylene envelope average linewidth was significantly lower for patients without rejection than those with (positive and negative predictive values of 90 and 91%, respectively).⁴³ Similar approaches have been used in the study of malaria⁴⁴ and for monitoring chemotherapy.⁴⁵

4 MODIFIED LIPOPROTEINS

LDL undergo a number of interactions that can potentially alter local lipid dynamics and/or tumbling of the entire particle. LDL particle tumbling rates can be greatly reduced by increasing the viscosity of the medium, by forming an LDL gel by ultracentrifugation, or by precipitation with heparin. The ³¹P NMR spectra of LDL gels have broad, powder-like lineshapes with the sign and magnitude of the anisotropy characteristic of the bilayer mesophase. This resonance narrows over the same temperature range as the core cholesterol ester liquid crystalline to liquid phase transition (5–45 °C), suggesting interactions between the surface and core in such gel samples. The ³¹P lineshapes of LDL–heparin insoluble complexes are also powder-like, but are broader than native LDL gels. Phosphorus-31 lineshape simulations suggest that insoluble complex formation slows phospholipid lateral diffusion in the LDL monolayer and alters the orientation and/or order of the headgroup.⁴⁶ Even soluble complexes of LDL formed by interaction with heparin (HEP) or chondroitin sulfate (CS) exhibit substantial increases in ³¹P linewidth with increasing HEP/LDL or CS/LDL ratio, a phenomenon related to the Stokes radius of the resulting complex.⁴⁷ The binding

of lipopolysaccharide (LPS) to LDL gives ³¹P spectra that suggest the motions of phospholipid polar headgroups are more restricted in the complex than in LDL alone;⁴⁸ however, the paramagnetic shift reagent, Pr³⁺, has the same effect on the LDL/LPS complex as it does on LDL alone, suggesting equivalent steric accessibility of phospholipid headgroups in both systems.⁴⁹

The oxidation of lipids and lipoproteins has taken on increased significance since the recent demonstration that increasing oxidation of LDL leads to decreasing uptake by the LDL cell surface receptor and increasing uptake by the scavenger receptor on macrophages; extensive intracellular cholesterol accumulation, foam cell formation, and atherosclerosis are the natural sequelae. Tumor necrosis factor (TNF- α) has been implicated in the oxidation of polyunsaturated fatty acids in the plasma of normal mice. When mice were injected with TNF- α , the intensity of the polyolefinic fatty acyl carbon resonance (~128 ppm) diminished significantly compared with the mono-olefinic resonance (~130 ppm).⁵⁰ Human LDL have been oxidized to different stages in vitro and ¹H, ¹³C, and ³¹P NMR have demonstrated changes in (a) mobilities of lipids, (b) lipid–protein interactions, (c) the abundance of conjugated and oxidienes, (d) polyunsaturated/monounsaturated fatty acid ratio, and (e) lyso-PC abundance.⁵¹ Similarly, in vitro oxidation of human HDL with Cu²⁺ studied by ¹H and ³¹P NMR demonstrated almost complete loss of polyunsaturated moieties, the appearance of fatty acid epoxide systems, and the formation of oxidized cholesterol derivatives.⁵²

Natural abundance ¹³C NMR spectra of lipoproteins yield little if any information about the protein moieties. One strategy for overcoming this limitation is to couple ¹³C-enriched reporter groups covalently to the apolipoprotein(s). A mild and minimally perturbing method for placing a reporter group on proteins involves the reductive dimethylation of lysine ϵ -amino groups. The resulting dimethyllysine (DML) moieties have pK_a values very similar to their unlabeled counterparts. This approach has been used to tag about 65% of the lysine residues of the major protein of LDL, apoB-100. The ¹³C spectrum of DML–LDL contains two new resonances (42.8 and 43.2 ppm) with different pK_a values (8.9, 10.5), suggesting two different types of microenvironments for the labeled lysines.⁵³ Methylation of LDL containing familial defective apoB-100 (Arg500 → Gln) results in a decreased abundance of DML residues with a pK_a of 8.9, demonstrating a remarkable sensitivity of this technique to the conformation of an extremely large (513 kDa) protein.⁵³ Methylation of apoE in canine HDL also results in two new resonances in the ¹³C spectrum of this modified lipoprotein. The two pools of DML titrate with pK_a values of 10.4 and 9.3. In contrast, eight different DML peaks (42.5–44.5 ppm) with pK_a values ranging from 7.8 to 10.5 are observed for apoE in discoidal complexes with dimyristoyl-PC (DMPC).⁵⁴

5 MODEL AND RECOMBINED LIPOPROTEINS

Model systems have been devised to probe features of lipid structural organization not readily observed in spectroscopic studies of intact lipoproteins. For example, the general organization of lipoproteins consists of a polar shell containing primarily surface-active lipids (e.g. phospholipids and cholesterol), and a core containing mainly weakly polar lipids (e.g.

cholesteryl esters and triglycerides). However, this structure does not readily explain the capacity of water-soluble lipid transfer proteins and lipolytic enzymes to interact with lipids localized predominantly in the core. The possibility that small amounts of weakly polar lipids might be present in the surface of lipoproteins has been investigated with model systems comprised of phospholipid bilayers and small proportions of ^{13}C -carbonyl labeled cholesteryl esters or triglycerides. Carbon-13 NMR studies of these systems revealed a low but finite solubility (2–3%) of each of these lipids in the phospholipid bilayer.^{55–58} Triglycerides and cholesteryl esters do not strongly compete for the interface and are expected to partition into the lipoprotein interface in proportion to their concentration in the core.⁵⁹ Unesterified cholesterol diminishes but does not prohibit the incorporation of triglycerides and cholesterol esters into phospholipid bilayers.⁶⁰ Weakly polar lipids in the surface monolayer of lipoproteins can be recognized by lipolytic enzymes and by cholesteryl ester transfer protein, which exchanges cholesteryl esters and triglycerides between lipoproteins. Similarly, microemulsions containing phospholipids and cholesteryl esters or triglycerides in proportions similar to their abundance in lipoproteins have been used to investigate surface–core interactions.⁶¹

Another use of model systems has been to study properties of minor lipid constituents such as fatty acids, whose NMR signals at natural abundance are too weak to detect. In this case, isotopic enrichment permits detection of the minor component. For example, fatty acids with ^{13}C enrichment of the carboxyl carbon have been used to monitor the ionization behavior of fatty acids and partitioning between the surface and core of lipoproteins. The apparent pK_a of oleic acid is different in HDL, LDL, and VLDL, decreasing with decreasing particle size.⁶² The apparent pK_a of oleic acid in VLDL and chylomicrons is similar to that in protein-free triglyceride rich emulsions.⁶³

Albumin transports lipids (primarily fatty acids) in blood and can be considered a lipoprotein.⁶⁴ In contrast to other plasma lipoproteins, the noncovalent complexes of fatty acids with albumin are comprised of only a few lipid molecules per protein molecule, and NMR signals of the fatty acid are detectable only with ^{13}C enrichment. Individual fatty acids with ^{13}C enrichment in a specific carbon can be added to fatty acid-free albumin for NMR studies. The spectrum of albumin complexed with a ^{13}C -carboxyl enriched long chain fatty acid such as oleic acid shows multiple fatty acid carboxyl resonances reflecting heterogeneous binding sites on albumin.⁶⁵ ^{13}C -carboxyl enriched fatty acids have been used to study lipid–protein interactions as a function of mole ratio of fatty acid, pH, fatty acid chain length, and temperature.^{66–69} Three high affinity sites for long chain fatty acids have been localized on bovine serum albumin by ^{13}C NMR studies of binding to proteolytic fragments.⁷⁰ Fatty acids ^{13}C enriched at positions C-3' and C-14' have allowed probing molecular motions of fatty acids while occupying specific binding sites.⁷¹ Fatty acid–albumin complexes represent a unique case in which lipid–protein interactions are defined in detail by NMR spectroscopy.⁶⁸ In contrast, the proteins in other native and model lipoproteins interact with many lipid molecules, making the study of detailed lipid–protein interactions by NMR much more difficult.

The effect of apoA-I on the structure and dynamics of the lipids in a DMPC/apoA-I (100:1 mole ratio) complex

has been studied above, at, and below the thermal transition of the complex (27°C).⁷² The ^{13}C resonance arising from the C-3' of the fatty acyl chains is a doublet, split by approximately 0.2 ppm, suggesting that the C-3' atoms occupy two magnetically inequivalent sites. Temperature dependent changes in chemical shifts and T_1 values reveal dynamic and conformational changes characteristic of gel to liquid crystalline phase transitions observed in pure phospholipid systems. For the DMPC/apoA-I complex at 37°C, the fatty acyl C-4'–C-11' methylene envelope and the C-7' and C-13' resonances occur at significantly higher frequencies than those of the corresponding envelope and resonances for the DMPC vesicle. These results suggest that the apoprotein rigidifies the acyl chains by increasing their number of *trans* conformers.⁷² The conformation of apoA-I in complexes containing 1-palmitoyl-2-oleoyl-PC (POPC) and cholesteryl oleate (CO) has been investigated in NMR studies of apoA-I ^{13}C methylated on its lysine side chains (DML). The observation of multiple resolved resonances at pH 10 with pK_a values ranging from 8.3 to 10.5 suggests that apoA-I assumes different conformations on differently sized discoidal particles. For two spherical populations, the titration behavior of these DML residues is essentially the same in the small and large spherical particles, indicating that apoA-I conformation is similar in these two populations.⁷³

ApoC-I contains a single methionine residue at position 38 that resides in a putative amphipathic helical segment that extends from Glu33 to Leu53. The involvement of the sequence around Met38 in phospholipid binding was evaluated by selective enrichment of the thiomethyl group with $^{13}\text{CH}_3\text{I}$.⁷⁴ The linewidth and spin–lattice relaxation time changes observed for the thiomethyl resonance of ^{13}C -enriched apoC-I suggests that Met38 resides in a region of the apoprotein that undergoes significant secondary and/or tertiary structural change upon unfolding in guanidine hydrochloride and upon refolding with phospholipid.

6 PEPTIDE FRAGMENTS OF APOLIPOPROTEINS

For NMR studies, several difficulties are encountered in studying lipid-free apolipoproteins such as their limited solubility and/or tendency toward extensive aggregation. Sometimes these difficulties can be overcome by using shorter synthetic peptide fragments. For example, 18-residue peptides of altered sequence have been used to model the 22-residue segments of apoA-I that readily form amphipathic helices in the lipid associated state.⁷⁵ The relative importance of the cationic side chains of lysine or the anionic side chain of glutamic acid were evaluated in terms of their effect on phospholipid structure and dynamics. Both the 'cationic interface' and 'anionic interface' peptides strongly disrupt phospholipid bilayer structure, as indicated by narrower ^1H and ^{31}P NMR resonances for the peptide–DMPC complexes than for DMPC bilayer vesicles. Motional properties of the polar headgroup suggest no strong interactions between the zwitterionic phospholipid headgroups and the side chains of polar amino acids of either peptide. Human apoC-II is a 79-amino acid apoprotein that reversibly binds to VLDL and HDL, and activates lipoprotein lipase, an enzyme that hydrolyzes primarily triglycerides. Lycksell and co-workers⁷⁶ have studied a 30-residue fragment, apoC-II (50–79), which

retains the capacity to activate lipoprotein lipase. Standard NOESY, COSY, and TOCSY experiments in water with hexafluoroisopropanol at 600 MHz were used to demonstrate the formation of a stable α helix from Ile66 to Gly77, and suggested the possibility of another α -helical turn between Lys55 and Ala59.

7 CONCLUSION

The remarkable versatility of NMR will likely stimulate continued studies of plasma lipoproteins as native particles in whole plasma or in the isolated state, as particles with specially modified moieties, and as model systems. The potential of high field multidimensional NMR is just beginning to be used to elucidate the structure of apolipoproteins which, to date, have been extremely difficult to study in biologically relevant systems. The use of perdeuterated lipids, and peptides covalently coupled to various lipid moieties affords additional advantages that should make it feasible to study the structure of apoproteins in at least quasi-native states.

1 INTRODUCTION

NMR spectra of small molecules dissolved in organic liquid crystalline media permit measurement of large numbers of intramolecular dipolar couplings that carry very precise information on molecular structure.^{1,2} However, for molecules with more than half a dozen protons, the strong degree of solute alignment obtained in such media typically results in a vast number of large, non-first-order splittings that make these spectra difficult to analyze. On the other hand, very weak alignment, caused by a molecule's own magnetic susceptibility anisotropy, also gives rise to measurable dipolar couplings.^{3,4} However, typically only the largest couplings are detectable and manifest themselves as small, field-dependent changes in the corresponding J splittings. The advantages of such ultra-weak alignment are that the NMR spectrum retains its regular high-resolution simplicity and that, owing to the extremely weak magnetic forces involved, it does not perturb the structure of the molecule.

Tolman et al.⁵ demonstrated that small dipolar couplings, on the order of a few hertz, could be measured for the backbone amides in paramagnetic myoglobin, and that these data correlate well with values expected on the basis of its crystal structure. Tjandra et al. subsequently measured a substantial number of very small ^{15}N – ^1H and ^{13}C – ^1H dipolar couplings in a diamagnetic protein-DNA complex and demonstrated that incorporation of these data as restraints in the structure calculation yields a remarkable improvement in both local and global geometry.⁶ In particular, by defining the relative orientation of structural elements in a macromolecule

with few interconnecting NOEs, these dipolar restraints solve a long-standing problem.

General applicability of the weak alignment approach greatly increased when the suitability of very dilute liquid crystalline media for this purpose was discovered.^{7–14} The macromolecules are dispersed in the aqueous phase that separates the highly ordered liquid crystalline particles, which have a spacing much larger than the diameter of the molecule under study. Despite the typically rather large macroscopic viscosity of such samples, the ordered particles are spaced by essentially pure water, and usually no adverse effect on rotational diffusion is therefore observed.⁷ However, exceptions to this rule can occur in cases where alignment is dominated by attractive electrostatic interactions between the nematogen and the solute.¹⁵ As discussed in Section 4.6, an alternate way for inducing weak alignment relies on axially compressed or stretched polyacrylamide gels. From a theoretical perspective, alignment in gels and in dilute lyotropic liquid crystalline suspensions are very similar.

The ability to tune the degree of macromolecular alignment over more than an order of magnitude, usually in the range from 3×10^{-4} to 3×10^{-3} , makes it possible to measure a whole plethora of short-range dipolar interactions, including those between directly bonded ^1H – ^{13}C , ^1H – ^{15}N , ^{13}C – ^{13}C and ^{13}C – ^{15}N pairs, and also between spatially proximate non-bonded ^1H – ^1H , ^1H – ^{13}C and ^1H – ^{15}N spin pairs.^{8,16–18} The measurement and application of dipolar couplings and CSA effects in weakly oriented macromolecules has already proven to be extremely useful in biomolecular structural studies. Several reviews have appeared on various aspects of this work,^{19–22} and further developments in this area of research are occurring at a very rapid pace. Even at present, a comprehensive review of this area would fill hundreds of pages, and is therefore well beyond the scope of this article. Instead, the relation between this work and conventional liquid crystal NMR will be highlighted, as well as illustrating some of the advantageous features of the weak ordering approach.

2 THEORETICAL CONSIDERATIONS

Although standard theory described for liquid crystals elsewhere in this encyclopedia is directly applicable to the case of very weakly ordered macromolecules, the early applications of the weak ordering technology derive from the magnetic-susceptibility induced alignment. As a result, the terminology differs somewhat and will be briefly reviewed below.

2.1 Dipolar Couplings in Aligned Macromolecules

The relation between the internuclear vector and the dipolar coupling between two spins, A and B can be found in numerous textbooks. For the purpose of deriving the resonance frequencies (i.e., dipolar splittings) only the z component of the local field of one nuclear dipole at the position of the second nucleus is relevant (secular approximation):

$$H_{dd} = D_{\max}^{AB} \langle I_{Az} I_{Bz} (3 \cos^2 \zeta - 1) \rangle \quad (1a)$$

where the $\langle \rangle$ brackets refer to the time or ensemble average, which are equivalent for isotropic and liquid crystalline

solutions, ζ is the angle between the $A - B$ internuclear vector and the magnetic field, and

$$D_{\max}^{AB} = \frac{-\mu_o(H/2\pi)\gamma_A\gamma_B}{(4\pi^2 r_{AB}^3)} \quad (1b)$$

is the static dipolar coupling in SI units (21.7 kHz for H–N pairs, assuming an internuclear distance $r_{NH} = 1.04 \text{ \AA}$). The constant, $-\mu_o$, is the magnetic permittivity of vacuum, h is Planck's constant, γ_X is the magnetogyric ratio of spin X , and r_{AB} is the distance between nuclei A and B . The residual dipolar splitting between spins A and B equals

$$D^{AB} = D_{\max}^{AB} \langle P_2(\cos \zeta) \rangle \quad (1c)$$

with $P_2(x) = (3x^2 - 1)/2$. Note that some texts differ in the definition of the dipolar coupling, D_{AB} , by a factor two.

If the molecule is rigid, the orientation of the internuclear vector, r_{AB} , in an arbitrary molecular coordinate system can be described by the angles α_x , α_y , and α_z between the vector and the x , y , and z axis of the coordinate system. The $P_2(\cos \zeta)$ term can be expressed as

$$\langle P_2(\cos \zeta) \rangle = \sum_{i,j=\{x,y,z\}} S_{ij} \cos \alpha_i \cos \alpha_j \quad (2)$$

where S is a traceless symmetric 3×3 matrix, commonly referred to as the Saupe matrix, the Saupe order matrix, or simply the order matrix.

If the structure of the molecule is known, i.e., $\cos \alpha_i$ factors in equation (2) are known, the five independent elements of S generally can be solved provided that dipolar couplings for at least five internuclear vectors are available. However, if any pair of internuclear vectors is parallel, and for other special cases such as a set that includes three mutually orthogonal interactions, more measured couplings are required. For macromolecules, many more dipolar couplings are frequently measured, and S is overdetermined. The Saupe matrix elements are then best determined using singular value decomposition.²³

The order matrix is real and symmetric, and it therefore is always possible to define a molecular axis system where S becomes diagonal. In a number of applications it can be advantageous to work in this principal axis frame, where D^{AB} now can be expressed in terms of the polar coordinates of the $A - B$ internuclear vector:

$$D^{AB}(\theta, \phi) = \frac{3}{2} D_{\max}^{AB} [\cos^2 \theta A_{zz} + \sin^2 \theta \cos^2 \phi A_{xx} + \sin^2 \theta \sin^2 \phi A_{yy}] \quad (3a)$$

where A is the diagonalized alignment tensor, with $|A_{zz}| > |A_{yy}| > |A_{xx}|$. This frequently is rewritten as

$$D^{AB}(\theta, \phi) = D_{\max}^{AB} \left[P_2(\cos \theta) A_a + \frac{3}{4} A_r \sin^2 \theta \cos 2\phi \right] \quad (3b)$$

where $A_a = 3A_{zz}/2$ is the axial component of the alignment tensor, and $A_r = (A_{xx} - A_{yy})$ is referred to as its rhombic component.

Note that the maximum value for A_a equals one when the z axis of the principal alignment tensor is fully aligned

with the static field. In practice, the dilute liquid crystal work discussed in this article concerns A_a values on the order of 10^{-3} . Equation (3b) is sometimes rewritten as

$$D^{AB}(\theta, \phi) = D_a^{AB} \left[(3 \cos^2 \theta - 1) + \frac{3}{2} R \sin^2 \theta \cos 2\phi \right] \quad (3c)$$

where $D_a^{AB} = 1/2 A_a D_{\max}^{AB}$ is referred to as the magnitude of the dipolar coupling tensor, frequently normalized to the N–H dipolar interaction, and $R = A_r/A_a$ is the rhombicity. Note that $0 \leq R \leq 2/3$.

2.2 Estimate for Alignment Tensor in Case of Unknown Structure

When working with a molecule of unknown structure, the above-described singular value decomposition approach for determining the order matrix is not applicable. However, as briefly discussed below, a reasonable estimate for the principal components of the alignment tensor can be obtained from the range and distribution of observed dipolar couplings.

First, it is convenient to normalize all observed one-bond and two-bond dipolar couplings to, for example, the N–H dipolar coupling, by multiplying the observed $P - Q$ dipolar coupling by $(\gamma_N \gamma_H r_{PQ}^3)/(\gamma_P \gamma_Q r_{NH}^3)$. Empirically determined optimum scaling factors are listed in Table 1. In the absence of measurement error in the dipolar couplings, the bond vector with the largest absolute value for the normalized dipolar coupling provides a lower limit for $2D_a^{NH}$ in equation (3c). Similarly, an estimate for the rhombicity R in equation (3c) can be obtained from the dipolar coupling value, D_{opposite} , with the other extreme value (negative for $D_a^{NH} > 0$; positive for $D_a^{NH} < 0$). The value of R itself, defined in this manner, is always positive and follows from $D_{\text{opposite}} = -D_a^{NH} [1 + 3/2R]$, or

$$R = -\frac{2}{3} \left[1 + \left(\frac{D_{\text{opposite}}}{D_a^{NH}} \right) \right] \quad (4)$$

This approach only uses the extreme values of the distribution of observed dipolar couplings. A more robust approach plots the histogram of the entire ensemble of normalized dipolar couplings.²⁴ Figure 1 shows an example of such histograms for the two globular domains of Ca^{2+} -ligated calmodulin. The histograms have been compiled from nearly complete sets of $^1D_{NH}$, $^1D_{C\alpha H\alpha}$, $^1D_{C'N}$, $^2D_{C'H\alpha}$ and $^1D_{C'C\alpha}$ couplings, recorded in a medium of filamentous phage *Pfl*.

Table 1 Magnitude of dipolar couplings relative to $^1D_{NH}$

	NMR ^a	X-ray ^b
$^1D_{C\alpha H\alpha}$	2.08	2.02
$^1D_{C\alpha C'}$	0.198	0.198
$^1D_{C'N}$	0.120	0.121
$^2D_{C'HN}$	0.300	0.319
$^1D_{CH3}$	0.628	0.628

^aValues that result in the lowest energy NMR structure of ubiquitin and yield best fit to $^{13}\text{C}'$ CSA.⁷⁴

^bOptimized by fitting experimental couplings to the ubiquitin X-ray structure.¹⁶

Figure 1 Histogram of normalized dipolar couplings measured in the N- and C-terminal domains of Ca^{2+} -ligated calmodulin, dissolved in a liquid crystalline medium containing 15 mg Pf1/ml and 10 mM KCl. Dipolar couplings are normalized relative to the one-bond ^{15}N - ^1H interaction. SVD fits to the crystal structure and the use of a freely floating alignment tensor during structure calculation⁷⁷ both yield $D_a^{\text{NH}} = 11.0 \text{ Hz}$; $R = 0.38$ and $D_a^{\text{NH}} = 10.1 \text{ Hz}$; $R = 0.66$ for the N- and C-terminal domains, respectively. Note that even while the two histograms cover the same width, they have considerably different asymmetries (rhombicity, R). A dearth of bond vectors parallel to the z-axis of the alignment tensor causes the absence of dipolar couplings $>22 \text{ Hz}$ for the N-terminal domain. Different types of dipolar couplings are shaded separately in the histograms: $^1D_{\text{NH}}$ – solid; $^1D_{\text{C}\alpha\text{H}\alpha}$ – shaded (///); $^1D_{\text{C}'\text{N}}$ – shaded (\\); $^1D_{\text{C}'\text{C}\alpha}$ – shaded (|||); $^2D_{\text{C}'\text{H}\alpha}$ – blank

It can be shown that for a uniform distribution of bond vectors, such a histogram will resemble the solid state powder pattern observed for chemical shift anisotropy.²⁵ In the present case, the singularities in the powder pattern correspond to D_{zz}^{NH} , D_{xx}^{NH} and D_{yy}^{NH} , with the condition that $D_{zz}^{\text{NH}} + D_{xx}^{\text{NH}} + D_{yy}^{\text{NH}} = 0$. The relation between the powder pattern singularities D_{zz}^{NH} , D_{xx}^{NH} , D_{yy}^{NH} and the parameters D_a^{NH} and R is given by:²⁴

$$D_{zz}^{\text{NH}} = 2D_a^{\text{NH}} \quad (5a)$$

$$D_{yy}^{\text{NH}} = -D_a^{\text{NH}}(1 + 1.5R) \quad (5b)$$

$$D_{xx}^{\text{NH}} = -D_a^{\text{NH}}(1 - 1.5R) \quad (5c)$$

If outliers appear to be present in the histogram, it is worth while checking the origin of these extreme dipolar couplings. They may correspond to $^1D_{\text{C}'\text{N}}$, $^2D_{\text{C}'\text{H}\alpha}$ or $^1D_{\text{C}'\text{C}\alpha}$ couplings derived from weak or partially overlapping correlations, and critical visual inspection of the raw data may be needed before including them.

3 MEASUREMENT OF DIPOLAR COUPLINGS

To date, measurement of dipolar couplings has focused primarily on one-bond interactions, which as a result of their known internuclear distance, are readily interpreted in terms of orientation. Also, they are generally the easiest to measure. Two-bond interactions also have the benefit of a fixed internuclear distance, but owing to their larger separation, they can be more difficult to measure at the same level of relative accuracy. New analysis schemes promise to make measurement of ^1H - ^1H dipolar couplings more straightforward, and they may also become popular as structural restraints.

Except for geminal ^1H - ^1H interactions and pairs of protons in structural elements of fixed geometry, the interproton distance is an additional parameter influencing the dipolar coupling. This therefore results in a less direct relation between the value of the coupling and the orientation of the corresponding vector. However, structure calculation programs such as CNS²⁶ can readily deal with this additional complexity.²⁷

So far, most measurements of dipolar couplings have focused on the one-bond and two-bond couplings along the polypeptide backbone in proteins (Figure 2), but dipolar couplings within and between sidechains are becoming increasingly used. Below, some of the most widely used techniques for measuring the various types of couplings are briefly discussed, with particular emphasis on ^{15}N - ^{13}C labeled proteins. With the exception of couplings between protons separated by more than three bonds, where the J coupling is usually negligible, the coupling observed in the liquid crystalline phase represents the sum of the scalar and dipolar contributions. Considerable variation in the scalar couplings frequently exists,

Figure 2 Protein backbone fragment, with dipolar interactions that can readily be measured marked by dashed lines. Although $D_{\text{NC}\alpha}$ can be measured experimentally, its relative accuracy tends to be lower, and for *trans*-peptide bonds its normalized value is very similar to that of $^1D_{\text{C}'\text{C}\alpha}$ of the preceding residue. $^1D_{\text{C}\alpha\text{C}\beta}$ is most useful in perdeuterated proteins, where no value for $^1D_{\text{C}\alpha\text{H}\alpha}$ can be measured and where the slow transverse relaxation of the deuterated $^{13}\text{C}\alpha$ permits its accurate measurement

making it necessary to measure the couplings both in the isotropic and aligned environment.

Two conceptually different approaches can be used for measurement of J or dipolar splittings. First, the splitting can be measured directly from a two- or three-dimensional spectrum recorded in the absence of decoupling of the interaction of interest. Frequently, an E.COSY,²⁸ S³E,²⁹ or IPAP version³⁰ of the multi-dimensional experiment is used in order to reduce overlap. Second, in a so-called quantitative- J correlation experiment,³¹ the size of the splitting can be derived from the intensity of a given resonance relative to that of a reference.

3.1 Accuracy of Measured Splitting

For splittings measured from relative peak displacements in the multi-dimensional NMR spectrum, the accuracy of a peak position is directly proportional to its signal-to-noise ratio, and inversely related to its line width. Although the accuracy also depends on the method used for peak position determination and on the digital resolution, a reasonable approximation for the root-mean-square uncertainty, ΔJ , in a measured splitting for a well resolved, undistorted, pure phase or pure antiphase doublet is given by:

$$\Delta J = \frac{LW}{SN} \quad (6)$$

where LW is the line width at half height (in the dimension where the splitting is being measured), and SN is the signal-to-noise ratio. Note that equation (6) provides a lower limit for the true accuracy of the measurement, because other distortions such as partial overlap or imperfect phasing can contribute to the error in a reproducible manner.

3.2 Measurement of $^1J_{\text{HN}}$

One-bond $^1D_{\text{NH}}$ dipolar coupling were the first ones to be measured in a weakly oriented protein, simply by recording a ^1H - ^{15}N HSQC spectrum without the regular ^1H 180° decoupling pulse applied at the midpoint of the t_1 evolution period. Transverse relaxation is considerably slower in the ^{15}N dimension compared to the ^1H dimension, and measurement in the indirect ^{15}N dimension is therefore preferred over measurement in the ^1H dimension. However, the spectral crowding doubles when HSQC spectra are recorded without decoupling, typically resulting in an unacceptable degree of resonance overlap.

A conceptually very simple method for measuring $^1J_{\text{NH}}$ separates the F_1 -coupled HSQC into two separate subspectra, containing only the upfield or downfield components of the F_1 ^{15}N - $\{^1\text{H}\}$ doublets. This is done by interleaving two experiments: one where the F_1 ^{15}N - $\{^1\text{H}\}$ doublets are in phase, and one where they are exactly antiphase. The sum of the antiphase and the in-phase spectra yields a spectrum containing only the downfield components, whereas the difference yields the upfield components (Figure 3). This approach is referred to as IPAP (for in-phase and anti-phase)³² and is easily extended to higher dimensionality experiments.

A small region of the two-dimensional ^1H - ^{15}N IPAP-HSQC spectrum of calmodulin is shown in Figure 3. Isotropic ^1H - ^{15}N J splittings are ca. 93 Hz, and the large deviations

Figure 3 Small region of the IPAP ^{15}N - ^1H HSQC spectrum of Ca^{2+} -ligated calmodulin in *Pfl* medium. The solid and dashed contours correspond to the downfield and upfield ^{15}N - $\{^1\text{H}\}$ doublet components, which are separated into two two-dimensional subspectra. These subspectra are superimposed in this plot for visual simplicity, as none of the resonances overlap one another in the displayed region of the spectrum. The size of the splittings are marked in the figure and correspond to $|^1J_{\text{NH}} + ^1D_{\text{NH}}|$

from this value correspond to the dipolar contributions to these splittings. So, both the sign and the magnitude of the dipolar coupling are obtained from such spectra.

3.3 Measurement of $^1J_{\text{C}'\text{C}\alpha}$

Due to the longer internuclear distance, and the lower product of the gyromagnetic ratios involved, the $^1D_{\text{C}'\text{C}\alpha}$ coupling is inherently five times smaller than the one-bond ^1H - ^{15}N coupling (Table 1). In order to obtain meaningful information, it therefore is necessary to measure this coupling at high accuracy. There are two ways to measure $^1J_{\text{C}'\text{C}\alpha}$: observation of the C' or of the C' resonance in the absence of decoupling the non-observed spin. For protonated proteins at moderate field strengths (≤ 14 T), the $\text{C}'T_2$ is invariably much longer than the $\text{C}^\alpha T_2$, favoring detection of C' for most accurate measurement of $^1J_{\text{C}'\text{C}\alpha}$. For perdeuterated proteins, detection of $^{13}\text{C}'$ in the presence of ^2H and $^{13}\text{C}^\beta$ decoupling yields narrower ^{13}C resonances, particularly at higher fields.

Usually, the most accurate method for measurement of $^1J_{\text{C}'\text{C}\alpha}$ is to simply record a 3D HNCO spectrum where the C^α pulse, normally applied at the midpoint of the $^{13}\text{C}'$ evolution period, is omitted.³³ The HNCO experiment yields among the best resolved triple resonance spectra and the two-fold increase in the number of resonances relative to the $^{13}\text{C}^\alpha$ -decoupled spectrum is generally not much of a problem. The $^{13}\text{C}'$ transverse relaxation rate is dominated by its chemical shift anisotropy, and $^{13}\text{C}'$ line widths at 600 MHz are about 30% larger than at 500 MHz ^1H frequency. It is therefore preferable to measure the $^1J_{\text{C}'\text{C}\alpha}$ splitting at a relatively low magnetic field strength.

3.4 Measurement of $^1J_{C'N}$ and $^2J_{CHN}$

Dipolar couplings across the peptide bond between $^{15}N_i$ and $^{13}C'_{i-1}$ are inherently 8.3 times weaker than $^1D_{NH}$ (Table 1). Therefore, accuracy of their measurement is critical for making optimal use of these small couplings in structure determination. Owing to the favorable relaxation properties of ^{15}N , especially when selecting the downfield ^{15}N - $\{^1H\}$ doublet component, the $^1J_{C'N}$ coupling is detected through the ^{15}N and not the $^{13}C'$ nucleus. The simplest method just records a two-dimensional HSQC on the $^{13}C/^{15}N$ doubly labeled protein, and inserts a $^{13}C^\alpha$ but not a $^{13}C'$ 180° decoupling pulse at the mid-point of ^{15}N evolution.³⁴ The resulting doublet in the ^{15}N dimension corresponds to $^1J_{C'N}$. Interestingly, the detected amide proton is also coupled to $^{13}C'$ (which has not changed its spin state during or after ^{15}N evolution). Therefore, the two doublet components are also displaced relative to one another by the $^2J_{CHN}$ coupling in the 1H dimension. Although normally this splitting would be very difficult to resolve because the $^1H^N$ line width is typically much larger than the $^2J_{CHN}$ coupling, the E.COSY principle²⁸ effectively separates the two $^1H^N$ - $\{^{13}C'\}$ doublet components (Figure 4).

An interesting alternative approach, based on the principle of quantitative J correlation, derives $^1J_{C'N}$ from the relative intensities of two interleaved 3D TROSY-HNCO spectra.³⁵ In one experiment (reference spectrum) the pulse scheme uses optimal one-bond ^{15}N - $\{^{13}C'\}$ dephasing of 33 ms, whereas in the second experiment (attenuated spectrum) the dephasing delay is set near the null condition (66 ms). Any deviation from $^1J_{C'N} + ^1D_{C'N} = (66 \text{ ms})^{-1}$ results in non-zero intensity in the second spectrum. The relative intensities of these two spectra then give a very precise measure for $^1J_{C'N}$, and permit

$^1D_{C'N}$ to be derived at an accuracy that is a fraction of a hertz, provided the signal to noise in the reference spectrum exceeds 20:1.

3.5 Measurement of $^1J_{C\alpha H\alpha}$ and $^1J_{C\alpha C\beta}$

Although, in principle, $^1J_{C\alpha H\alpha}$ can be measured from a 1H - ^{13}C two-dimensional correlation spectrum, recorded in the absence of heteronuclear decoupling in either the F_1 or F_2 dimension, the increase in spectral crowding frequently leads to unacceptable overlap for all but the smallest proteins. In practice, therefore, $^1J_{C\alpha H\alpha}$ is most commonly measured either from a series of J_{CH} -modulated HSQC spectra, simultaneous to measurement of sidechain J_{CH} couplings (see below), or from a H^α -coupled HN(CO)CA or (HA)CA(CO)NH spectrum. This latter experiment makes it easy to decouple the $^1J_{C\alpha C\beta}$ coupling by using a constant-time C^α evolution period, and is therefore preferred when dealing with small or medium-size proteins. Its pulse sequence is identical to a scheme previously used for measuring relaxation interference between the $^{13}C^\alpha$ CSA tensor and the $^{13}C^\alpha$ - $^1H^\alpha$ dipolar interaction,³⁶ but now it is the splitting itself rather than the difference in doublet intensities that is the focus of the measurement.

In perdeuterated proteins, $^1J_{C\alpha H\alpha}$ is inaccessible, but the long $^{13}C^\alpha$ transverse relaxation time permits measurement of $^1J_{C\alpha C\beta}$ from a regular HNCA experiment, recorded in the presence of 2H decoupling during $^{13}C^\alpha$ evolution.³⁷

3.6 Measurement of Sidechain $^1J_{CH}$ Couplings

To date, most attention has focused on measurement of backbone-related dipolar couplings. Nevertheless, dipolar couplings also are starting to become used for studying sidechain conformations. However, a significant fraction of the sidechains may be subject to rotameric averaging, which reduces the dipolar coupling relative to a static, single conformation. If the smaller dipolar coupling is imposed during structure calculation as if it were rigid, this can result in distorted sidechain conformations with high energy. A way around this is to impose the observed dipolar coupling as a lower bound for the true dipolar coupling.³⁸ An even better way would be to evaluate for each site separately what the degree of sidechain mobility is by conducting the requisite relaxation experiments.

For small and medium-size proteins, an accurate way for extracting both backbone $^1J_{C\alpha H\alpha}$ and sidechain $^1J_{CH}$ couplings is the recording of a set of CT-HSQC spectra, in which the 1H 180° decoupling pulse is systematically shifted. The intensity modulation pattern observed in the fully decoupled CT-HSQC spectrum then provides an accurate measure for $^1J_{CH}$. For methylene groups, the modulation frequency corresponds to the sum of the two $^1J_{CH}$ couplings. Methyl group intensities are modulated by $^1J_{CH}$ and by $3 \times ^1J_{CH}$, with amplitudes of the modulation having a ratio of approximately 1:3. As a result of the rapid three-fold rotation about the three-fold symmetry axis of the methyl group, the $^1D_{CH}$ dipolar coupling is scaled down by -0.31 relative to its static value.³⁹ Figure 5 compares the $^1D_{CH}$ and $^1D_{CC}$ dipolar couplings for methyl groups in ubiquitin. The tight correlation seen in this figure testifies to the precision at which these dipolar couplings can be measured. As suggested by this figure, for structure calculation

Figure 4 Small region of the ^{15}N - 1H HSQC spectrum of the first immunoglobulin binding domain of protein G, recorded in the absence of $^{13}C'$ decoupling in *Pf1* liquid crystal (11 mg ml^{-1}). The vertical and horizontal displacements within each doublet correspond to $^1J_{C'N} + ^1D_{C'N}$ and $^2J_{CHN} + ^2D_{CHN}$, respectively. Doublets are labeled by their one-letter residue type and number

Figure 5 Plot of $^1D_{CH}$ versus $^1D_{CC}$ residual dipolar couplings of methyl groups in the protein ubiquitin, dissolved in a liquid crystalline medium containing 5% (w/v) bicelles. The solid line represents the best fit of the data by linear regression, with a slope of -3.17 ± 0.03 . The outlier, labeled A46, corresponds to an alanine residue with a positive ϕ angle, for which there is a steric clash between the methyl group and a backbone carbonyl oxygen. (Reprinted, with permission, from Ottiger et al.³⁹)

purposes the methyl group $^1D_{CH}$ value may be converted into $^1D_{CC}$, thereby restraining the C–C(H₃) orientation.

For larger proteins, the lower sensitivity and increased spectral overlap in a CT-HSQC spectrum frequently result in a relatively small fraction of residues for which the $^1J_{CH}$ coupling can be measured. As an alternative, spectra recorded with CCH-COSY or HCCH-COSY, without decoupling in the detected dimension may be used for measurement of J_{CH} . An additional benefit of this approach is that for the case of non-equivalent methylene protons, both J_{CH} couplings can be measured separately. In favorable cases, the 1H – 1H multiplet structure in such spectra also permits measurement of $^2J_{HH}$.⁴⁰

3.7 Measurement of 1H – 1H Couplings

The history of measuring 1H – 1H J couplings is particularly rich and has been reviewed in numerous places. The E.COSY approach, applied in either a homo- or heteronuclear manner has proven particularly useful in this respect.²⁸ However, few of these methods are suitable for measurement of 1H – 1H dipolar couplings. When oriented, 1H – 1H multiplet structure tends to become very complex as a result of the multitude of coupling partners any given proton experiences. Fortunately, in heteronuclear type E.COSY spectra this does not pose a serious problem, and the utility of triple resonance experiments for measurement of both the sign and magnitude of intraresidue and sequential $J_{H\alpha HN}$ couplings has been demonstrated in oriented media.⁴¹ Nevertheless, with some exceptions,^{42,43} such experiments tend to be less suitable for measurement of dipolar couplings that are spatially proximate but far apart in the covalent bond network. Alternatively, the popular HNHA experiment can be used for measuring 1H – 1H dipolar couplings that involve an amide proton.^{6,44} In this experiment, the magnitude of $|J_{HH} + D_{HH}|$ is derived from the diagonal to cross peak intensity ratio. So, except for the intraresidue

H^N – H^α interaction, where there also is a significant scalar contribution to the interaction, the sign of D_{HH} is not available from this experiment.

4 ALIGNMENT MEDIA FOR MACROMOLECULES

A prerequisite for studying macromolecules in a liquid crystalline phase is that the order imposed on the macromolecule is very small, typically less than 0.002. The order of the liquid crystal particles themselves is invariably much higher, in the 0.5–0.85 range. Clearly, for achieving such a weak solute alignment in the strongly oriented liquid crystalline medium, interaction between the macromolecule and the liquid crystal must be very weak. The medium must also be aqueous, such that the proteins or nucleic acids remain in their natural environment. An efficient way to satisfy these conditions is the use of a very dilute ($\leq 10\%$ (w/v)) lyotropic nematic liquid crystalline suspension, where the nematogenic unit itself is a large particle. In a liquid crystalline phase, the weak steric and electrostatic interactions between liquid crystal particles cause their cooperative alignment. There is a lower limit for the nematogen concentration, c_n , required to form a stable liquid crystalline phase. If the sample is diluted below this threshold, it separates into an isotropic phase with concentration c_i and a nematic phase, with the c_n being 5–20% higher than c_i . The aspect ratio of the nematogenic particle is a critical determinant for the lowest concentration at which liquid crystalline ordering occurs. The time needed for formation of a homogeneous liquid crystalline phase strongly depends on the nematogen concentration, and can be very long for concentrated samples, but also for samples that are close to the threshold concentration, where separation between microscopic aligned and isotropic domains takes place.

All liquid crystalline media that have proven to be useful for weak ordering of proteins and nucleic acids consist of large ($> 1000 \text{ \AA}$), water-soluble particles, with relatively low surface charge densities ($\leq 0.5 e \text{ nm}^{-2}$). The interaction between the liquid crystal particles results in increased macroscopic viscosity relative to pure water. However, rotational diffusion of the macromolecule itself is virtually unchanged, unless it has a weak affinity for the liquid crystal particle. In the latter case, the degree of order typically is much too large and therefore is of little practical interest. For all lyotropic liquid crystals discussed below, the degree of order imposed on the solute can be adjusted by changing the concentration of the liquid crystal itself over the range where it yields an ordered phase. There is not yet a single, ideal liquid crystal. For example, phospholipases without inhibitors cannot be studied in bicelles as they break down the phospholipids; active proteases can destroy phage-based liquid crystals; other proteins may stick to phospholipids, or the surface charge distribution of the liquid crystal may cause too strong an electrostatic interaction with the solute. Also, liquid crystals require some degree of surface charge to keep their order and may fail to remain liquid crystalline at high salt concentrations. Below, several of the most widely used systems are briefly discussed.

4.1 Bicelles

Bicelles were the first liquid crystalline medium used for weak alignment of proteins and DNA.^{7,8} These are planar

bilayered particles that usually consist of regular saturated phospholipids. Most commonly, a mixture of dimyristoyl phosphatidyl choline (DMPC) and dihexanoyl phosphatidyl choline (DHPC) is used. DMPC makes up the bilayer, which constitutes the plane of the bicelle, and the DHPC detergent protects the long DMPC alkyl chains at the rims of the bilayer from exposure to solvent. Bicellar liquid crystals were originally developed by Prestegard, Sanders and co-workers for the purpose of studying lipophilic molecules, anchored in these highly ordered membranes.^{45,46} The DMPC/DHPC combination was found to be particularly robust. When raising the temperature above 25 °C, the system switches from isotropic to a nematic liquid crystalline phase.⁴⁷ This temperature corresponds to the melting temperature of DMPC, i.e., the temperature at which the saturated alkane chains of DMPC melt from a crystalline or gel state, in which the alkane chains are all *trans*, to a flexible, liquid crystalline phase. Near this transition temperature, the sample has high macroscopic viscosity and tends to be slightly opaque. Below 25 °C the solution remains clear and unordered and both small angle neutron scattering and NMR diffusion experiments indicate the bicelles to be disk-shaped bilayers in this unordered phase.^{48,49}

The phase diagram of the DMPC/DHPC mixture is very complex and depends on a large number of variables, including the absolute concentration, the molar ratio $[\text{DMPC}]/[\text{DHPC}] = q$, temperature, ionic strength, and on the presence of charged amphiphilic molecules such as sodium dodecyl sulfate (SDS) or cetyl trimethylammonium bromide (CTAB). Bicelles were long believed to remain disk-shaped above the DMPC melting temperature, with a diameter determined by q . However, the diameters predicted by such a model are incompatible with the very dilute concentrations (down to $\leq 2\%$ (v/v)) at which the sample remains liquid crystalline. Recent tracer diffusion obstruction and neutron scattering data indicate the liquid crystalline phase to consist of highly porous bilayers, presumably with the detergent covering the rims of the pores.^{49,50}

Intrinsically, DMPC/DHPC bicelles can form a liquid crystalline phase over the temperature range of 25–45 °C. However, near the lower end of this range (25–30 °C), dilute samples tend to be unstable and they frequently separate into an aligned and an isotropic phase. This can be prevented by addition of a small molar fraction (typically 1–3%, relative to DMPC) of charged amphiphiles, such as CTAB (positive) or SDS (negative).⁵¹ Alternatively, charged phospholipids such as dimyristoyl phosphatidylserine (negative), or dimyristoyl trimethylammonium propane (positive) can be used. Charging the bicelles in this manner helps prevent phase separation and widens the part of the phase diagram over which the liquid crystalline phase remains stable. The electrostatic potential repels and attracts oppositely charged groups on the solute, and generally causes a change in both the orientation and magnitude of the alignment tensor. This can be a highly beneficial side effect, as it permits measurement of dipolar couplings under multiple orientations of the protein (Figure 6).⁵² Usually, this change in orientation is approximately linear with charge. So, if more than two different samples are prepared in this manner, they simply yield alignment tensors that are linear combinations of one another.⁵³

Regular phospholipids are subject to acid- and base-catalyzed hydrolysis of the carboxyester linkage between the

Figure 6 Orientations of the Gln⁴⁰ N–H vector in ubiquitin compatible with the ¹⁵N–¹H one bond dipolar coupling measured in undoped bicelles (band A) and in positively charged bicelles (band B). Orientations are given in the coordinate frame of the X-ray structure of this protein. Heavy lines correspond to the measured dipolar couplings; thinner lines correspond to orientations if D_{NH} is increased or decreased by 1 Hz. The solid dot marks the orientation of the N–H vector when the protons are model-built into the crystal structure, assuming H^{N} is located on the line bisecting the $\text{C}'\text{--N--C}^{\alpha}$ angle. (Adapted, with permission, from Ramirez and Bax⁵²)

alkyl chain and the glycerol backbone. The rate of hydrolysis is minimal at pH 6.5, but rapidly increases once the pH differs by more than one unit from this value.⁵⁴ Use of ether lipids, where the carboxyester bond is replaced by an ether linker can prevent this hydrolysis and such samples can be stable over a very wide range of pH^{55,56} for periods of several years.

The temperature range over which the bicelles are liquid crystalline can be extended either by introducing a small fraction of mono-unsaturated DMPC, which lowers the melting temperature of the alkane chain,⁵⁴ or by using shorter alkane chains. Use of shorter alkane chain phospholipids, such as dilauroyl PC (12-C chains)⁵⁷ or ditridecanoyl PC (13-C chains)⁵⁵ lowers the transition temperature by about 12 and 6 °C, respectively, and increases the upper temperature limit as well. However, the macroscopic viscosity of these solutions below the transition temperature tends to be much higher than for DMPC/DHPC bicelles, such that preparation of the sample can be more cumbersome, particularly when using a microcell.

4.2 Filamentous Phage

Use of a liquid crystalline solution consisting of filamentous phages for aligning macromolecules was introduced in 1998.^{9,10,58} Clore et al. used a medium based on the filamentous phage *fd*, and also demonstrated the potential of tobacco mosaic virus (TMV). The Pardi group demonstrated the utility of the phage *Pfl*, which is similar to *fd*, but which at a contour length of ca. 2 μm is nearly twice as long. Both phages have a diameter of 6.5 nm, and are quite rigid, with a persistence length of ca. 1 μm . As a result of the high aspect ratios of these particles, solutions can remain liquid crystalline down to very low concentrations, as low as a

few mg ml^{-1} . Although it was suggested that liquid crystallinity is independent of ionic strength, we find this to be true only at higher phage concentrations,¹⁵ whereas at lower concentrations ($\sim 13 \text{ mg ml}^{-1}$ for *Pfl*) the degree of alignment becomes sensitive to ionic strength, and at very high salt concentrations the samples become isotropic. In contrast to *fd*, *Pfl* solutions tend to remain homogeneous when their concentration is lowered below the nematic threshold concentration, c_n . However, below this threshold, the degree of both phage and solute alignment becomes a function of the magnetic field strength, characteristic of a so-called paranematic phase.¹⁵

The negative surface charge (ca. $0.5 e \text{ nm}^{-2}$) is necessary to maintain a uniform suspension of these large particles. When lowering the pH below 6, partial protonation of the glutamate and aspartyl sidechains of the phage coat protein reduces the net charge of the virus particle and the phage precipitates. However, *fd* has been shown to be soluble and liquid crystalline when the pH is reduced further, to ca. 3.⁵⁹

As highlighted by Clore et al. for an immunoglobulin-binding domain of Streptococcal protein G, the alignment tensor in the phage medium can be very different from that in the bicelle medium.¹⁰ This is advantageous as it permits measurement of dipolar couplings relative to two independent axis systems, thereby resolving much of the degeneracy that occurs in interpreting a dipolar coupling in terms of two orientational variables, θ and ϕ in equation (3c). The phage particles are aligned with their long axis parallel to the magnetic field. Therefore, if the alignment of solute macromolecules were caused exclusively by steric interaction, the alignment tensor would be very similar to that in the bicelle medium. In practice, the alignment tensors in phage and bicelle media tend to be quite different as there usually are relatively strong electrostatic interactions between the phage and the solute (see also Section 5).

4.3 Alkyl-poly(ethylene glycol) Based Media

A lyotropic liquid crystal consisting of a mixture of alkyl-poly(ethylene glycol) and hexanol is another very useful medium for protein and nucleic acid alignment.¹⁴ Alkyl-poly(ethylene glycol) type compounds generally do not tend to bind to proteins, making this an attractive medium for a wide range of biological systems. In contrast to bicelles, the liquid crystal is not subject to hydrolysis and it can remain stable for years, provided the concentration of hexanol does not decrease as a result of slow evaporation. The medium remains liquid crystalline over a wide pH range and a considerable temperature range of $10\text{--}40^\circ\text{C}$, which is tunable by varying the type of alkyl-poly(ethylene glycol) and the chain length of the alcohol.¹⁴

The different alkyl-poly(ethylene glycol) compounds are referred to as *CmEn*, where *m* is the number of carbons in the alkyl group, and *n* is the number of ethylene glycol units. Typically, a hexanol to C_{12}E_5 molar ratio of 0.96 (5 wt.% C_{12}E_5 in H_2O) is used yielding a particularly stable liquid crystal that is easy to prepare, but the medium is relatively tolerant to changes in the absolute and relative concentrations. C_{12}E_5 is commercially available at low cost. In many cases, the sample can simply be recovered from the liquid crystal by extensive dialysis.

4.4 Other Liquid Crystals

Ternary mixtures of cetylpyridinium chloride (CPCl) or bromide (CPBr), hexanol, and NaCl or NaBr in water can form stable liquid crystalline phases over a wide range of conditions. Prosser et al.¹¹ demonstrated that the CPCl version yielded alignment for the protein ubiquitin, and Barrientos et al.¹² described the use of the CPBr based medium. Remarkable differences were found between the CPBr and CPCl based liquid crystals, with CPBr being more suitable for low ionic strength measurements ($10\text{--}40 \text{ mM}$ NaBr) and the CPCl system requiring higher salt concentrations ($200\text{--}500 \text{ mM}$ NaCl).¹²

Dilute suspensions of natural cellulose fibers, derived either from wood pulp or from filter paper by careful sulfuric acid hydrolysis, also can form a liquid crystalline phase suitable for macromolecular ordering.⁶⁰ Although negatively charged, the net surface charge density is lower than for filamentous phage, making it a useful complement to the other media, mentioned above. However, the lower surface charge and the smaller aspect ratio relative to filamentous phage result in a higher minimal threshold concentration for liquid crystal formation.

A suspension of purple membrane (PM) fragments has also been shown suitable for inducing a weak degree of macromolecular order.^{53,61} These fragments consist primarily (75% (w/w)) of bacteriorhodopsin, an integral membrane protein with seven transmembrane helices. The PM fragments have an average diameter of about $1 \mu\text{m}$. This is sufficiently large that the total magnetic susceptibility anisotropy of such a particle causes it to align nearly 100% when placed in a strong magnetic field ($\geq 11 \text{ T}$), with the membrane plane orthogonal to the direction of the magnetic field.⁶² So, in contrast to the bicelle, phage and CPBr systems, PM does not need to form a liquid crystalline phase for obtaining alignment.

The strong net negative surface charge of PM causes very weak transient binding of solute proteins that carry clusters of positively charged groups on their surfaces, and thereby can result in net alignment.^{53,61} The electrostatic interactions are typically weak enough not to distort the structure of globular proteins. However, as is the case with all liquid crystal studies in this chapter, when studying flexible regions in a protein, care must be taken when interpreting the dipolar coupling data as the protein only transiently interacts with the liquid crystal. Interaction with the nematogen may be favored when the flexible region temporarily adopts a given shape, whereas other, non-binding conformations of the flexible region may not be sampled.

4.5 Polyacrylamide Gel

In order to prevent sedimentation, suspensions of large particles such as phages, bicelles, and cellulose require a repelling interaction, i.e., a net surface charge. These local electrostatic fields generally result in stronger solute alignment, which then may become too strong for facile dipolar coupling measurement. In other cases, solutes may cause the liquid crystal particles to aggregate and precipitate. For example, no stable liquid crystal has yet been described that is suitable for detergent-solubilized proteins. So, although the above mentioned liquid crystalline systems will cover the majority of systems of interest, there remain exceptions.

Recently, a very useful alternative method for inducing weak alignment has been developed that is known as strain-induced alignment in a gel (SAG).^{63,64} This method relies on anisotropically compressed polyacrylamide gel, which forms an extremely stable and inert aqueous matrix for solute proteins, and even permits their study under partially or fully denaturing conditions.⁶⁵ The gels may either be compressed or stretched in the axial direction,⁶⁴ with stretching generally yielding stronger alignment.⁶⁶ The robustness of such a medium makes it particularly useful for challenging applications such as detergent-solubilized systems.⁶⁶ The solutes may either be diffused into the gel, or they may be included in the medium before polymerization of the hydrogel is induced.

Compression of the gel can simply be achieved by first casting it in a narrow diameter (3–3.5 mm) cylinder. Then, after soaking in the solute of interest, it is transferred to a regular 4.2-mm inner diameter (ID) NMR sample tube, followed by axial compression by a susceptibility-matched plunger. Stretching can be achieved by radial compression, using a funnel-like device to squeeze a larger diameter gel (5–7 mm) into a regular 4.2-mm ID NMR sample tube.⁶⁶ Polyacrylamide gels appear to yield the most widely applicable method for inducing weak macromolecular alignment as the system is very inert and stable. Their principal disadvantage is a potential decrease in rotational diffusion rate of the solute, resulting in line broadening.^{64,67} This latter effect can be minimized by using gel concentrations as low as possible ($\leq 5\%$) combined with high degrees of stretching, and by using low cross-linking ratios ($\leq 1:40$).

4.6 Use of Multiple Alignment Media

As discussed in Section 5, solute alignment is defined by both steric and electrostatic interaction. So, by using nearly neutral liquid crystals, such as bicelles or the alkyl poly(ethylene-glycol) medium, and a charged medium such as phage or the cetyl-pyridinium based phase, a single molecule can be studied using two or more independent alignment tensors. As illustrated in Figure 6, this removes much of the degeneracy in the relation between dipolar coupling and internuclear vector orientation.⁵² A dipolar coupling measured in a given medium defines the internuclear vector to be on one of two oppositely oriented cones. The alignment tensor in a second medium will generally be oriented differently relative to the molecular frame and a dipolar coupling defines the same vector to be situated on a different cone. The true internuclear vector orientation then must be located on one of the intersections between the two sets of cones (Figure 6). In the general case of a non-axially symmetric (rhombic) alignment tensor there are up to eight intersections. If a third, independent alignment tensor can be obtained, this degeneracy may be reduced to two-fold. The true orientation and its inverse can never be distinguished from measurements on a single dipolar interaction, and two-fold degeneracy is therefore the best that can be achieved for a single vector.

Besides changing the liquid crystal medium, the alignment tensor may also be altered by subtly changing the protein. For example, when the pH is altered such that the surface charge distribution becomes different, this will affect the alignment tensor in the charged liquid crystalline media. Similarly, if

protein preparations are available with and without a His-tag tail, their alignment tensors will generally be different, although not necessarily by a large amount. Also, for a protein with a His-tag, a relatively small change in pH from 6 to 7.5 can significantly alter the alignment tensor.

If one-bond dipolar couplings are measured for a set of non-collinear interactions in a fragment of known secondary structure, such as an α -helix, there are four different ways to orient the fragment relative to the alignment tensor. Dipolar couplings measured in a second, independent medium, can lift this degeneracy, defining its orientation uniquely.⁶⁸

5 RELATION BETWEEN ALIGNMENT AND SHAPE

Tjandra et al. demonstrated that in a bicelle medium the principal axes of the molecular alignment tensor closely coincide with those of the rotational diffusion tensor.^{8,69} This shows that in this nearly neutral medium, alignment is defined by the solute's shape. As mentioned above, the alignment tensor can be modified by adding a net charge to the bicelles, by doping them with either CTAB (+) or SDS (−). This demonstrates that electrostatic interactions also play a role. In fact, for an oriented medium of strongly negatively charged, rod-shaped viral particles, or oriented PM fragments, electrostatic interactions usually dominate alignment of solute proteins.

A simple steric model has been proposed that quantitatively describes the relation between the solute's shape and its alignment in the type of lyotropic liquid crystals described in this article.⁷⁰ So far, it has only been demonstrated for the case of (nearly) neutral particles, such as bicelles, but preliminary results indicate that the method can be extended to account for the effect of charge.

In the so-called steric-obstruction model, the solute sample can be simulated as a collection of randomly oriented, uniformly distributed molecules, from which the fraction that sterically clashes with the ordered array of liquid crystal particles is removed. For example, for a lamellar phase such as bicelles or $C_{12}E_5$, a larger fraction of molecules oriented orthogonal to the bilayer will be obstructed than molecules parallel to the surface, resulting in net ordering of the remaining, non-obstructed molecules. For each non-obstructed molecule a Saupe order matrix is calculated, using equation (2). Averaging of the Saupe matrices for all non-obstructed proteins then yields the sterically predicted alignment tensor.⁷⁰ In an extension of this method that accounts also for the effect of electrostatics, different weighting factors are given to each of the non-obstructed solute molecules, depending on the Boltzmann factor calculated when taking the electrostatic potential into account (M. Zweckstetter, unpublished results).

Figure 7 shows the correlation between the ^{15}N - 1H dipolar couplings measured for the Ig binding domain of Streptococcal protein G, and that predicted from its 1.0 Å crystal structure, using an alignment tensor that is not best-fitted to the data, but calculated on the basis of its shape.⁶⁹ When ignoring electrostatics, the predicted alignment tensors for bicelle and phage media are very similar. However, the experimentally observed dipolar couplings in the two media are very different and, as expected, good agreement is only observed for the bicelle medium (Figure 7). When electrostatic terms are included in the calculations for the phage medium, the

Figure 7 Correlations between experimental $^1D_{\text{NH}}$ values and values calculated from the shape-predicted alignment tensor of the third immunoglobulin binding domain of protein G in (a) 5% (w/v) bicelle medium, and (b) 28 mg ml $^{-1}$ *fd* medium. Dashed lines correspond to $y = x$. The poor correlation in (b) indicates that in phage medium the protein alignment is dominated by electrostatic interactions, which are ignored in the alignment tensor prediction, and not by steric interaction. (Adapted, with permission, from Zweckstetter and Bax¹⁵)

agreement becomes nearly as good as for the neutral bicelle medium. Note that in contrast to the results of an SVD fit, the data shown in Figure 7 do not include any adjustable parameters. So, the alignment tensor orientation and magnitude are calculated on the basis of the protein's shape, and

subsequently dipolar couplings are predicted on the basis of the orientation of the internuclear vector relative to this alignment tensor.

6 STRUCTURE VALIDATION

One particularly attractive feature of dipolar couplings is that they can be used in a very direct manner to evaluate the accuracy of any given structure: the more accurate the structure, the better the agreement is between experimental dipolar couplings and this structure. In order to evaluate this agreement, one first needs to determine the alignment tensor or Saupe matrix. As mentioned earlier, there are two conceptually different ways to do this. One can either predict the alignment on the basis of the molecule's shape and charge distribution, or one can determine the Saupe matrix elements of equation (2) simply by singular value decomposition. There are five independent elements in the Saupe matrix. If the number of experimentally measured independent (i.e., non-collinear) dipolar interactions is much larger than five, the SVD approach is preferred as it eliminates the effect of errors in the shape-predicted alignment tensor. Clearly, for effective validation it is necessary that the number of observables (dipolar couplings) is much larger than the number of variables in the SVD fit. If this condition is not met, corrections can be made for the significance of the correlation in terms of F statistics. For proteins, typically the number of observed dipolar couplings is much larger than five, and the goodness of the fit provides a direct measure for the accuracy of the structure.

Figure 8 shows a typical example of the correlation between measured dipolar couplings and those predicted by two structures of the C-terminal domain of Ca $^{2+}$ -calmodulin (after best fitting the Saupe matrix to the experimental couplings). The first correlation (Figure 8a) is calculated by using the 1.0-Å X-ray crystal structure of *Paramecium tetraurelia* calmodulin to fit the data measured for the highly homologous mammalian protein. It yields a Pearson's correlation coefficient, R^P , of 0.95. The second structure was calculated on the basis of N-H, C'-N, H $^{\alpha}$ -C $^{\alpha}$ and C'-C $^{\alpha}$ dipolar couplings, and the H $^{\alpha}$ -C' couplings are best-fit to this structure. Clearly, the NMR structure ($R^P = 0.98$) predicts the experimental H $^{\alpha}$ -C' couplings better than the X-ray structure, which is related to a slight rearrangement of relative helix orientations in solution relative to the crystalline state.⁷¹

When accurate experimental dipolar couplings are available, it is always advantageous to incorporate them into the structure calculation process. However, once this is done, they no longer are useful for validation purposes. A way around this is to compare the observed and predicted changes in chemical shift between isotropic and aligned samples for a type of nucleus with a well-defined chemical shift anisotropy. The first application of this idea was for the change in ^{15}N chemical shift with field strength in a small protein-DNA complex,⁷² caused by the anisotropy of the magnetic susceptibility of this complex. Although the changes were minute (≤ 5 ppb), a clear improvement in the correlation was observed upon incorporation of dipolar couplings in the structure calculation process. Subsequently, comparison of much larger $^{13}\text{C}'$ chemical shift changes between a protein in isotropic and aligned bicellar medium also showed an excellent correlation with structure.⁷³

Figure 8 Correlation between measured, normalized $^2D_{C'H\alpha}$ dipolar couplings and those predicted by the 1.0-Å X-ray crystal structure (a), and by the NMR structures of the C-terminal domain of Ca^{2+} -calmodulin, calculated without $^2D_{C'H\alpha}$ couplings (b). The slightly better fit to the NMR structure is caused by a small rearrangement of the relative helix orientations in solution relative to those observed in the crystalline state of this protein⁷¹

7 CONCLUDING REMARKS

The introduction of methods for generating tunable, very weak alignment of macromolecules makes it possible to measure the one-bond and other short range dipolar couplings with a remarkable degree of accuracy. Even while the splittings are reduced by about three orders of magnitude relative to their static values, the narrow line widths and relatively high signal-to-noise ratio in high resolution NMR more than compensate for the low degree of order. For example, one-bond ^{15}N - ^1H dipolar couplings typically can be measured with an accuracy of ca. 0.1 Hz, whereas their range covers up to 50 Hz. Even for the intrinsically much smaller interactions, such as the one-bond ^{15}N - $^{13}\text{C}'$ dipolar coupling, the error typically is smaller by up to two orders of magnitude relative to the range of couplings observed. Similarly, chemical shift effects can be measured at a relative accuracy that rivals that attainable in solid state NMR, but the problem of resonance overlap is much less severe because isotropic shifts in solution are more effective at dispersing NMR spectra. Experimental correlations between $^{13}\text{C}'$, ^{15}N , and $^1\text{H}^{\text{N}}$ CSA tensors and secondary structure in proteins could be clearly established from such data.⁷⁴

Dipolar couplings are not very sensitive to small amplitude oscillations about an average orientation. Conversely,

relatively small discrepancies between observed and predicted magnitudes of dipolar couplings require rather large amplitude angular fluctuations if this discrepancy is entirely attributed to dynamic effects.^{75,76} Nevertheless, because averaging of the observed dipolar interactions is sensitive to motions that cover the entire time scale from milliseconds to femtoseconds, it can potentially provide a powerful complement for the study of dynamic processes.

Measurement of tensorial interactions in macromolecules is a new and rapidly expanding area in structural biology. It offers numerous new opportunities, including rapid determination of backbone folds, rapid structure determination, refinement of conventional NMR structures, and the study of relative orientations of components in multi-molecular complexes. It is likely that a further marriage between conventional solid-state NMR techniques and the weak alignment approach may expand these areas even further.

1 INTRODUCTION

The mycoplasmas are a diverse group of prokaryotic microorganisms that lack a cell wall. Since the mycoplasmas are genetically and morphologically the simplest organisms capable of autonomous replication, they provide useful models for the study of a number of problems in molecular and cellular biology. Mycoplasmas are particularly valuable for studies of the structure and function of cell membranes. Being nonphotosynthetic prokaryotes, as well as lacking a cell wall or outer membrane, mycoplasma cells possess only a single membrane, the limiting or plasma membrane. This membrane contains essentially all the cellular lipid, and, because these cells are small, a substantial fraction of the total cellular protein is membrane protein. Because of the absence of a cell wall, substantial quantities of highly pure membranes can usually be easily prepared by gentle osmotic lysis followed by differential centrifugation, a practical advantage not offered by other prokaryotic microorganisms.¹⁻³

Another useful property of mycoplasmas is the ability to induce dramatic yet controlled variations in the fatty acid composition of their membrane lipids. Thus, relatively large quantities of a number of exogenous saturated, unsaturated, branched-chain, or alicyclic fatty acids can be biosynthetically incorporated into the membrane phospho- and glycolipids of these organisms. In cases in which de novo fatty acid biosynthesis is either inhibited or absent, fatty acid-homogeneous membranes (membranes whose glycerolipids contain only a single species of fatty acyl chain) can sometimes be produced. Moreover, by growing mycoplasmas in the presence or absence of various quantities of cholesterol or other sterols, the amount of these compounds present in the membrane can be dramatically altered. The ability to manipulate membrane lipid fatty acid composition and cholesterol content, and thus to alter the phase state and fluidity of the membrane lipid bilayer, makes these organisms ideal for studying the roles of lipids in biological membranes.¹⁻³

The unique advantages of mycoplasmas for membrane studies, especially for studies of membrane lipid organization and dynamics, have induced a large number of investigators to study these microorganisms using a wide variety of physical techniques. For this reason, we probably know more about the physical properties of lipids in mycoplasma membranes in general, and in the *Acholeplasma laidlawii* membrane in

particular, than in any other biological membrane.¹⁻³ In this review we will briefly summarize the results of ^2H and ^{19}F NMR spectroscopic studies of the organization of the hydrocarbon chains of the lipids of the *A. laidlawii* membrane as determined by the chemical composition of the lipid bilayer and by the presence of membrane proteins.

2 ^2H NMR STUDIES OF THE *A. LAIDLAWII* MEMBRANE LIPIDS

The technique of ^2H NMR spectroscopy has proven to be of great value in studies of lipid conformation, orientational order, and dynamics in lipid bilayers and natural membranes.⁴⁻⁹ This technique has been widely used to study lipid hydrocarbon chain orientational order and dynamics in model and biological membranes, particularly in the membrane of *A. laidlawii*. In addition to being relatively nonperturbing, the deuterium nucleus, having a low natural abundance, can be selectively placed at various positions in the fatty acyl chain. Furthermore, the electric quadrupole moment of deuterium allows a direct measurement of the molecular order parameter of the lipid hydrocarbon chain, a measure of the time-averaged orientation relative to the bilayer normal, from the observed quadrupole splittings. Direct measurements of the rates of motion (relaxation times) of the hydrocarbon chains of the *A. laidlawii* membrane lipids, the other component of fluidity, have not yet been made by ^2H NMR. However, such determinations have been made for lipid model membranes and for the membranes of another mycoplasma (see below). The only significant disadvantage of deuterium is its low sensitivity, which until recently required the presence of relatively high probe levels (typically 50 mol% or more) in the membrane of interest.

2.1 Effect of Lipid Fatty Acid Structure

Oldfield et al. were the first to apply ^2H NMR to the *A. laidlawii* membrane.¹⁰ These workers selectively labeled the entire membrane lipid hydrocarbon chain by growing this organism in the presence of exogenous, fully deuterated lauric or palmitic acids. The ^2H NMR spectra obtained from isolated membranes, recorded at the growth temperature of 37°C, consist of a broad, unstructured envelope of numerous overlapping resonances. Nevertheless, the spectral shape observed is qualitatively that expected from the simultaneous presence of both lamellar gel and liquid crystalline lipid phases, in agreement with previous calorimetric and X-ray diffraction studies for *A. laidlawii* membranes enriched with saturated fatty acids.

Stockton et al. pioneered the use of specifically deuterated fatty acids in NMR studies of biological membranes.¹¹ *A. laidlawii* membranes were highly enriched by the biosynthetic incorporation of exogenous palmitic acid labeled only at the terminal methyl group with deuterium, and ^2H NMR spectra were recorded at a variety of temperatures. Although instrumental limitations precluded direct observation of the broad gel-phase signal present at lower temperatures, the intensity of the liquid crystalline spectra, which first appear at 20°C, increases with increasing temperature from 20 to 44°C. At 37°C, about half the lipid appears to exist in the

fluid state. Above 44 °C, the orientation order decreases fairly rapidly with increasing temperature.

Stockton et al. later extended the above study to include palmitic acid probes labeled at a variety of positions from C-2 through C-16 of the hydrocarbon chain.¹² In this study, both the gel and liquid crystalline spectra could be observed directly and the phase boundaries assigned in the previous study could thus be confirmed. In addition, the orientational order parameter profile for lipid existing just above the upper boundary of the lipid phase transition could be determined. It was found that a plot of order parameter versus the position of the deuteron in the chain reveals a 'plateau' region of roughly constant order extending from C-2 through C-10, after which the order parameter declines progressively more rapidly toward the methyl terminus, just as observed with model membranes composed of dipalmitoylphosphatidylcholine (DPPC) above their phase transition temperature.⁴⁻⁹ Using the fully deuterated palmitic acid probe, it was also shown that the effect of cholesterol on the liquid crystalline membrane lipids is to increase orientational order, particularly in the plateau region.

The spectrum of membranes enriched with 2,2-dideuteropalmitate differed from all other probes tested in revealing an unusual lineshape which appeared to consist of three overlapping powder doublets, whereas all other positions produced single doublet signals. These authors suggested that these multiple signals, which are also observed in C-2-labeled synthetic phospholipid liquid crystalline bilayers systems, could be due to differences in the initial conformation of the two acyl chains, to differences in the polar lipid headgroups, or to the presence of membrane protein. This first suggestion has since been confirmed by ²H NMR and by X-ray and neutron diffraction studies of model membranes, which have revealed that the fatty acyl chain at the 1-position of the glycerol backbone projects directly downward toward the bilayer core, while the chain esterified at position 2 begins nearly parallel to the bilayer plane before binding to become perpendicular to the bilayer plane at the C-2 position of the hydrocarbon chain.⁶⁻⁸ Three signals are observed because the C-2 chain may exist in one of two forms within the generally preferred conformation, the orientational orders of these two forms being significantly different. Subsequent studies by Rance et al. demonstrated that the conformations of the membrane lipids in the region of the C-2 position are qualitatively similar for all the various lipid classes and that the presence of membrane protein has little if any effect on these conformations.¹³

The properties of the gel and liquid crystalline lipid domains of the *A. laidlawii* membrane were subsequently studied in more detail by Smith et al.¹⁴ Membranes enriched with 13,13-dideuteropalmitic acid at 45 °C, just above the calorimetrically determined upper phase transition boundary, exhibit an almost perfect powder pattern, characteristic of fluid lipid bilayers with only a single quadrupole splitting, just as in the case of the total membrane lipids dispersed in water. Thus the presence of the membrane protein does not perturb the average orientational order of the lipid hydrocarbon chains and the lipid molecules must be exchanging rapidly on the NMR timescale between the bulk and protein boundary lipid domains. These results contrast with those obtained by electron spin resonance (ESR) spectroscopy using nitroxide fatty acid probes, where the presence of membrane protein appears to immobilize and disorder the lipid hydrocarbon chains and where the exchange between bulk and boundary lipid domains

is slow on the ESR timescale.¹⁵ Within the calorimetrically determined phase transition boundaries, separate gel and liquid crystalline spectral components coexist, indicating that the lipids of these domains are in slow exchange ($<10^5$ times s^{-1}). At the lower boundary of the phase transition, the gel state spectrum indicates a distribution of order parameters, the average being about one-half of the theoretical maximum for totally immobilized chains in the all-*trans* extended conformation. As the temperature is lowered still further, the observed quadrupole splitting eventually approaches its theoretical maximum, but only at temperatures well below the phase transition lower boundary. These authors suggested that the membrane lipid hydrocarbon chains exist in the all-*trans* extended conformation as they enter the gel state but continue to undergo rapid rotational motion about their long axes, this rotational motion being slowly decreased with further decreases in temperature. This interpretation has been challenged by Pink and Zuckerman, who have presented theoretical and reviewed experimental data indicating that transitions between different chain rotational conformational states, through the formation of *gauche* bonds, do occur in gel-state lipids, although on a rapid timescale compared with the ²H NMR timescale.¹⁶ However, the early Raman spectroscopic studies of model membranes on which this argument is based, and which indicate substantial numbers of *gauche* conformers in the gel, are not correct, and recent Fourier transform infrared spectroscopic studies indicate that few if any *gauche* conformers are present below the phase transition temperature.^{17,18} Thus the original ²H NMR interpretations appear to be correct.

Generally similar results were reported for a ²H NMR study of *A. laidlawii* membranes highly enriched (≥ 90 mol%) in myristic acid by Jarrell et al., except that the length of the plateau region of the order parameter profile appeared to be shortened somewhat compared with membranes enriched in palmitic acid.¹⁹ In addition, although the average order parameters of liquid crystalline hydrocarbon chains were the same in intact membranes as in an aqueous dispersion of membrane lipids, an increase in *linewidth* of about 20% was detected in the membrane, indicating that the presence of membrane proteins increases the heterogeneity of order distribution without affecting its average value. Furthermore, in the gel state a small fraction of lipid hydrocarbon chains in the membrane (but not in the lipid-water dispersion) remain disordered near their methyl terminal region, even at very low temperatures, indicating a small membrane-protein disordering effect. Finally, the gel state of membranes highly enriched in myristic acid was found to be more highly ordered than previously observed for membranes less highly enriched in myristic acid, suggesting that fatty acid heterogeneity may affect lipid gel state organization more than the presence of protein.

Rance et al. have also investigated the orientational order of *A. laidlawii* membranes enriched in unsaturated instead of saturated fatty acids, utilizing biosynthetically incorporated, specifically deuterated, oleic acid.²⁰ The orientational order of the oleoyl chain was determined at a variety of temperatures from -50 to +41 °C. Above 10-15 °C, a single, sharp quadrupolar powder pattern was observed for all C²H₂ segments except the C-9 and C-10 positions (and of course the C-2 segment). The C-9-C-10 spectra appear to consist of two overlapping powder patterns of equal integrated

intensity, indicating motional inequivalence of the C-9 and C-10 deuterons. This could only occur if the *cis*-double bond is not parallel to the bilayer normal, but instead it is slightly tilted. Below 10–15 °C, a second, broader spectral component, due to gel-phase lipid, begins to appear and grow at the expense of the liquid crystal component as the temperature is reduced. These spectra indicate that the center of the solid–fluid phase transition is about –12 °C, in good agreement with differential scanning calorimetry (DSC) studies. As noted in previous ^2H NMR studies, some relatively rapid hydrocarbon chain rotation, at least in the terminal half of the chain, persists down to –30 to –35 °C, well below the lower boundary of the calorimetrically detectable phase transition, and this was again ascribed to a disordering effect of the membrane protein.

A plot of orientation order parameter versus oleoyl chain position revealed a profile parameter somewhat different from that previously observed with palmitate-enriched *A. laidlawii* membranes. Instead of a plateau region extending from C-2 to C-10, the oleate-enriched membranes exhibit a shortened plateau region extending only to about C-7, followed by a 'dip' in the profile with a local minimum at C-10, after which the order parameters again increase before falling off toward the methyl terminus of the oleoyl chain. Although this profile would appear to indicate a markedly decreased order in the center of the oleoyl chain compared with palmitate, in fact this behavior is due largely to the geometry of the double bond and its tilted alignment with respect to the bilayer normal. Actually, the fluctuations about the average orientation of this segment of the oleoyl chain appear to be rather similar to the corresponding region of the palmitoyl chain if compared at the same reduced temperature (i.e., at the same temperature relative to the phase transition temperature). The major effect of the presence of the double bond then seems to be to cause a local organizational perturbation in its immediate vicinity, which, although not profound, is sufficiently strong to cause the formation of predominantly fluid rather than predominantly gel-state lipid at physiological temperatures.²⁰

The temperature dependence of the order parameters of the various C^2H_2 segments of the oleoyl chains was also determined in the study summarized above. The temperature dependence in the liquid crystalline state was approximately linear, with order decreasing with increasing temperature. In absolute terms, the change in order parameter with temperature was greatest in the plateau region (here C-2–C-6 or C-7) and smallest at the methyl end of the hydrocarbon chain. The opposite was true, however, if the change in order parameter with temperature was expressed as a percentage change in the quadrupolar splittings observed. Similar findings were also made for *A. laidlawii* membranes highly enriched in fully perdeuterated palmitic acid.²¹

Monck et al. have recently employed ^2H NMR spectroscopy to determine the orientational order parameter profiles of *A. laidlawii* membranes containing equimolar amounts of perdeuterated palmitic acid and an unsaturated fatty acid.²² These workers showed that at the optimal growth temperature of this organism of 37 °C, the chain-averaged order parameter values decreased in the order perdeuterated palmitic acid plus elaidic > oleic > linoleic acid, as expected from the increasing potency of a single *trans*, a single *cis*, or two *cis*-double bonds in lowering the phase transition temperature of the *A. laidlawii* membrane lipids. The chain-averaged order parameter value also decreases as the perdeuterated

palmitic acid/oleic acid ratio of the membrane lipids decreases. Again, order parameter profiles are essentially identical in intact membranes and in bilayers prepared from the total membrane lipids, demonstrating the absence of an effect of membrane proteins on average hydrocarbon chain orientational order. It was found that only a certain range of membrane lipid hydrocarbon chain orientational order is compatible with optimal membrane function and cell growth.

Jarrell et al. studied the orientational order and dynamics of *A. laidlawii* membranes enriched with a cyclopropyl-containing fatty acid by ^2H NMR.²³ Specifically, dihydrosterculic acid (*cis*-9,10-methyleneoctadecanoic acid), specifically deuterated at several positions along the chain, was biosynthetically incorporated into the membrane lipids of this organism. The transition from the gel to the liquid crystalline phase was determined to occur from –15 to 0 °C, a range somewhat narrower than, but with a midpoint similar to, that found for membranes enriched with oleic acid. The acyl chains of dihydrosterculic acid-containing membranes are less mobile in the gel and in the liquid crystalline state than those of oleic acid-containing membranes. Above 0 °C, the lipids are in the liquid crystalline phase and give rise to powder spectra characteristic of axially symmetric motion. The overall ordering is greater everywhere than that of oleoyl chains and features a maximum at the cyclopropyl moiety, in contrast to the plateau found with saturated chains. Detailed analysis of the data for the cyclopropane ring indicates that the C-9–C-10 bond is inclined at 89° relative to the director of motional averaging, in sharp contrast to the 3° estimated for oleic acid in the same membranes. These authors suggest that the replacement of a *cis*-double bond by a *cis*-cyclopropane ring in the lipid fatty acyl chains of eubacterial membranes gives rise to a less fluid lipid bilayer with generally similar but not identical physical properties.

It should be noted that in all of the ^2H NMR studies reviewed thus far, the *A. laidlawii* membranes highly enriched in palmitic acid residues behave in all respects quite similarly to DPPC model membranes, whereas the *A. laidlawii* membranes enriched in palmitate and oleate are very similar in behavior to bilayers of 1-palmitoyl-2-oleoylphosphatidylcholine. This finding supports the suitability of simple phospholipid bilayer membranes as reasonable models for more complex biological membranes, at least as far as hydrocarbon chain orientation and dynamics are concerned. Moreover, Kang et al. showed that the ^2H NMR spectra of freshly isolated or lyophilized membranes (enriched with specifically deuterated myristic or palmitic acids) and aqueous dispersions of the total membrane lipids are identical.²⁴ Together, these findings emphasize that the presence of membrane proteins has only a small effect on the average organization of membrane lipid fatty acyl chains, at least on the NMR timescale.

2.2 Effect of Lipid Bilayer Cholesterol Content

The effect of the presence of cholesterol on the orientational order of palmitate-enriched, oleate-enriched, and dihydrosterculate-enriched *A. laidlawii* membranes has been studied in some detail by Rance et al., Davis et al., and Jarrell et al., respectively.^{20,21,23} In fully perdeuterated palmitate-containing membranes, the incorporation of relatively large amounts of cholesterol (39 mol%) essentially

abolishes a discreet gel-to-liquid-crystalline phase transition, as detected by both ^2H NMR and DSC. Between 20 and 45 °C, the normal boundaries of the lipid phase transition in palmitate-enriched membranes not containing cholesterol, the cholesterol-enriched membranes exhibit an order parameter profile qualitatively similar to that normally observed for the liquid crystalline phase in the absence of cholesterol. However, the cholesterol-containing membranes have a higher average order and an extended plateau region. In absolute terms, the increase in order is greatest in the plateau region and smallest at the methyl end of the chains, although the reverse is true if the increase in order is expressed in percentage terms. Below 20 °C, the ^2H NMR spectra of cholesterol-enriched membranes are multicomponent, suggestive of complex motional and/or phase behavior. In oleate-enriched and dihydrosterculate-enriched *A. laidlawii* membranes, the order parameters of the various segments of the oleoyl or dihydrosterculoyl chain increase more or less linearly with cholesterol concentration from 0 to 27 mol%. The effect of cholesterol on the liquid crystalline order parameter profile is quite similar to that just described for palmitate-enriched membranes. Interestingly, the temperature dependence of the ^2H NMR spectra, and the NMR-determined phase transition position and width characteristic of oleic acid-enriched and dihydrosterculic acid-enriched membranes lacking cholesterol, are very little affected by the presence of up to 27 mol% cholesterol. This is in contrast with the ^2H NMR and calorimetrically reported behavior of palmitate-enriched membranes, and with the behavior of cholesterol in DPPC model membranes as determined by DSC and other techniques, where similar amounts of cholesterol significantly broaden the gel-to-liquid-crystalline phase transition and may also alter the phase transition midpoint temperature.²⁶

Huang et al. recently employed ^2H NMR spectroscopy to study the effect of cholesterol and lanosterol on the orientational order and dynamics of the lipid hydrocarbon chains of another mycoplasma, the *Mycoplasma capricolum* membrane.²⁷ As reported previously for *A. laidlawii*, the incorporation of increasing quantities of cholesterol increases the order of the lipid hydrocarbon chain at the optimal growth temperature of 37 °C and abolishes the formation of gel-state lipid at lower temperatures. As well, the presence of high levels of cholesterol abolishes the temperature dependence of the spin lattice (T_1) and the transverse (T_{2e}) relaxation times. In contrast, the incorporation of comparable amounts of lanosterol is much less effective in this regard. The average order and T_1 values of the hydrocarbon chains in isolated membranes and total membrane-lipid dispersions are comparable at a given temperature and cholesterol level, indicating that the presence of membrane protein has little effect on the average orientation or on the rates of the fast motions of the lipid hydrocarbon chains. In contrast, the T_{2e} values of the isolated membranes are much smaller than those of the total membrane-lipid dispersions, indicating that the presence of membrane proteins introduces a slow motion of the various phospholipid molecules which is not present in their absence. Markedly reduced T_{2e} values are also observed upon the addition of integral transmembrane proteins to model lipid bilayer membranes.⁸ The growth rates of *M. capricolum* cells are positively correlated with the relatively more ordered and less dynamic state of the membrane-lipid hydrocarbon

chains induced by the incorporation of increasing quantities of cholesterol.

Monck et al. have recently presented DSC and ^2H NMR spectroscopic evidence for the existence of two pools of cholesterol in the *A. laidlawii* membrane.²⁸ Membranes from cells grown in the presence of large amounts of exogenous cholesterol contain as much as 40 mol% cholesterol according to chemical determinations. However, the ^2H NMR-determined order parameter profiles and the DSC-determined thermotropic phase behavior indicate that cholesterol is present at significantly lower levels (10–15 mol%) in the lipid bilayer of this membrane. A further incorporation of cholesterol into the *A. laidlawii* membrane lipid bilayer was found to occur when cells or isolated membranes were exposed to high temperature. Deuterium NMR spectra of membrane preparations containing deuterium-labeled cholesterol indicate that most of the cholesterol present in the nonbilayer pool exists in a solid form. However, the exact nature and location of this second pool of membrane-associated cholesterol remains to be determined.

2.3 Effect of Lipid Polar Headgroup Structure

Eriksson et al. recently studied the hydrocarbon chain orientational order and dynamics of the major glucoglycerolipids of the *A. laidlawii* A membrane using ^2H NMR spectroscopy and biosynthetically incorporated perdeuterated palmitic acid.²⁹ The hydrocarbon chains of monoglucosyl diacylglycerol (MGDG) in lipid–water dispersions were found to exhibit a higher degree of orientational order than those of the diglucosyl diacylglycerol (DGDG) but the MGDG chains appeared to undergo a larger amplitude of slow reorientational motion than the DGDG chains, due perhaps to an increased rate of bilayer fluctuation or lateral diffusion over a curved bilayer surface. Interestingly, similar results have been reported for aqueous dispersions of synthetic phosphatidylethanolamines (PEs) and phosphatidylcholines (PCs), with the former exhibiting the larger degree of hydrocarbon chain order and slow-motion fluctuation. Since both MGDG and PEs are membrane lipids with relatively small, poorly hydrated, but strongly interacting, polar headgroups, that tend to form nonlamellar phases at higher temperatures, these authors suggest the relatively high orientational order of the MGDG hydrocarbon chains and their greater amplitude of collective motions may be related to the tendency of this lipid to induce curvature and instability into the liquid crystalline bilayer phase, due to its inverted cone shape. However, Monck et al. showed that phosphatidylglycerol, which is a bilayer-forming lipid, has a comparable order parameter profile to MGDG of similar fatty acid composition, suggesting that lipid shape may not be the only relevant variable.²² Wieslander et al. had previously used ^2H NMR (and ^1H NMR) spectroscopy to show that MGDG (or mixtures of MGDG and DGDG), isolated from *A. laidlawii* membranes enriched in oleic acid, can form reversed cubic as well as reversed hexagonal phases when dispersed in water.³⁰

3 ^{19}F NMR SPECTROSCOPY OF MEMBRANE LIPIDS

The technique of ^{19}F NMR spectroscopy has recently been applied to the *A. laidlawii* membranes by McDonough

et al.³¹ and Macdonald et al.³² In these studies small amounts of palmitic acid probes containing a single fluorine atom at various positions along the hydrocarbon chain were biosynthetically incorporated into the membrane lipids. The much greater sensitivity of the ¹⁹F compared with the ²H nucleus in the NMR experiment allows usable information to be collected with only small incorporations of probe (5–10 mol%), thus allowing the study of membranes that are very highly enriched in a variety of other exogenous fatty acids. This technique also avoids the laborious and expensive synthesis of a complete series of specifically deuterated fatty acids for each exogenous fatty acid to be studied, which had been necessary in previous ²H NMR studies. Other potential advantages include the ability to determine order parameters in the gel state and to study the rates of motion of various segments of the hydrocarbon chains via relaxation measurements. Physical, biochemical, and biological evidence was presented that the biosynthetic incorporation of this monofluoropalmitic acid does not greatly perturb the structure or function of the *A. laidlawii* membrane.

The orientational order parameter profiles of *A. laidlawii* membranes highly enriched in pentadecanoic, methyl isopalmitic, methyl anteisopalmitic and palmitelaidic acids were studied by ¹⁹F NMR as a function of temperature in the liquid crystalline state.³² In this series of fatty acids, which have nearly the same effective chain lengths, the effect of the presence of a methyl group substitution or of a *trans*-double bond on chain order could be determined. At all temperatures the *n*-saturated and methyl-branched fatty acid-enriched membranes exhibit the typical plateau profile already described for palmitic acid-containing membranes, whereas the palmitelaidic acid-enriched membranes show a progressive decrease in order on going from near to the carbonyl function toward the methyl terminus, without a clear-cut plateau region. At the growth temperature of 37 °C the chain-average order parameter values decrease in the order pentadecanoic > isopalmitic > anteisopalmitic > palmitelaidic acid-enriched membranes, which is also the order of decreasing phase transition temperatures as determined by DSC. Thus, at a constant absolute temperature (37 °C), the introduction of a methyl isobranched, a methyl anteisobranched or of a *trans*-double bond into an *n*-saturated fatty acyl chain results in progressively more disorder of the liquid crystalline bilayer hydrocarbon core. Interestingly, however, if the chain-average order parameters are compared at comparable reduced temperatures (i.e., at similar temperatures relative to their phase transition temperatures), then the results are exactly opposite to those obtained at 37 °C.

Experimental and theoretical results indicate that the rotation of the membrane lipid hydrocarbon chains in the gel state remains sufficiently rapid to allow for complete motional averaging and thus axially symmetric spectra on the ¹⁹F NMR but not the ²H NMR timescale.³³ This permits a detailed determination of the orientational order of the C–F bond in fluoropalmitic acid-labeled gel-state lipid in model and biological membranes, which is not possible with ²H NMR. Macdonald et al. thus determined the orientational order parameter profiles of *A. laidlawii* membranes highly enriched in a number of linear, saturated, methyl iso- and anteiso-branched, and *cis*- and *trans*-monounsaturated and cyclopropyl fatty acids.^{34–38} The effect of the position of the *cis*- or *trans*-double bond within the membrane lipid hydrocarbon chain on gel-state order was determined as

well.^{35,36} These workers found that at temperatures below the phase transition temperature, all types of hydrocarbon chains are relatively highly ordered, but that there are much larger differences between the chain-average order of different classes of fatty acids in the gel and in the liquid crystalline state. At comparable reduced temperatures in the gel state, order parameter values decrease in the order pentadecanoic > isopalmitic > palmitelaidic > anteisopalmitic > palmitoleic acid. This decreasing sequence of orientational order correlates well with the decreasing phase transition temperatures of the membrane lipids determined by DSC. Thus, membrane lipids whose hydrocarbon chains can pack in the most highly ordered array exhibit the most stable, highest-melting gel states. However, the membrane lipids with the highest phase transition temperatures form the least ordered liquid crystalline states once melting occurs. This is probably because at the higher temperatures necessary to induce melting of the more stable gel phases, the increased thermal energy possessed by the fluid hydrocarbon chains produces higher rates of motion and lower orientational order than is the case for membranes having lower phase transition temperatures. Although the detailed chemical structure of the fatty acyl group also has an effect on chain order, the lipid phase transition is the prime determinant of this parameter. For a more detailed summary of ¹⁹F NMR studies of the relationship between fatty acyl chain structure, orientational order, and lipid phase state in *A. laidlawii* membranes, the reader is referred to reviews by Macdonald et al.^{34,39}

Macdonald et al. also compared the orientational order parameter profiles and the chain average order values for intact *A. laidlawii* cells, isolated membranes, and total membrane-lipid dispersions having the same lipid polar headgroup and fatty acid compositions.³² They found that all three systems behave identically within the experimental error of their determinations. Thus the presence of cytoplasmic or membrane protein does not appear significantly to perturb membrane-lipid hydrocarbon chain organization in either the gel or the liquid crystalline states, a result in agreement with the ²H NMR studies reviewed earlier.

1 INTRODUCTION

Membrane proteins are responsible for many important biological functions, including some that are unique, such as those of receptors and ion channels, as well as some that overlap with those of soluble proteins, such as enzymes. Even though more than half of all proteins are associated with membranes, and there are many additional reasons to be interested in their structural biology, only a few high-resolution structural studies of membrane proteins have been reported.^{1–4} This is largely because samples of membrane proteins are problematic for the most commonly used methods of structural biology. Proteins complexed with lipids are difficult to crystallize in forms suitable for X-ray diffraction and conventional multidimensional solution NMR methods are hampered by their slow overall reorientation rates. However, in spite of its limitations, NMR spectroscopy has played an important role in the characterization of membrane proteins and, more importantly, it has the potential to play a dominant role in future studies. The development of high-resolution solid state NMR methods gives NMR spectroscopy sufficient versatility to determine the structures and describe the dynamics of proteins in bilayer samples. Further development of the instrumentation and methods for multidimensional solution NMR spectroscopy will also improve its effectiveness in studies of membrane proteins in micelle samples.

The key to NMR studies of membrane proteins is sample preparation.⁵ Figure 1 illustrates the molecular arrangements in phospholipid bilayers and detergent micelles, the two well-characterized model membrane systems used in a wide variety of biophysical investigations including NMR spectroscopy. Each micelle, of detergents most commonly used in NMR studies, contains approximately 50–60 single chain lipid molecules and a single polypeptide. In contrast, lipid bilayers are very large supramolecular structures with many phospholipid and polypeptide molecules in extended two-dimensional arrays. Proteins in micelles reorient relatively slowly, although rapidly enough to be suitable for most heteronuclear multidimensional solution NMR experiments in high-field spectrometers, while those in bilayers are immobile on the relevant

Figure 1 Schematic drawings of a protein in membrane environments: (a) detergent micelle; (b) phospholipid bilayer

NMR timescales, enabling them to be treated spectroscopically as solids. Therefore, the most important advantage of utilizing these two different types of model membrane is that they permit the use of both high-resolution solid state NMR and multidimensional solution NMR methods with membrane proteins. The results from these two essentially independent spectroscopic approaches can be combined to describe structural features of membrane proteins that are otherwise inaccessible to any single method of structure determination. Solid state NMR spectroscopy of oriented and unoriented bilayer samples and multidimensional solution NMR spectroscopy of micelle samples are most effective when the proteins are suitably labeled with stable isotopes and the samples are carefully prepared. The dynamics of backbone and side-chain sites can be described over a wide range of timescales through the analysis of nuclear spin relaxation in both micelle and bilayer samples, and motionally averaged powder pattern lineshapes in bilayer samples.⁶ Local protein motions have a dramatic effect on many spectral parameters; therefore mobile residues in loop and terminal segments can be readily identified in both types of sample.^{7,8}

2 EARLY NMR STUDIES OF MEMBRANES

NMR spectroscopy was applied to proteins within a decade of its initial demonstration. The first NMR spectrum of a protein reported in 1957 was that of a small globular protein, ribonuclease, in aqueous solution.⁹ This spectrum, despite its low sensitivity and limited resolution, encouraged additional development by demonstrating the basic feasibility of NMR spectroscopy for the study of proteins in aqueous solution. However, the development and application of NMR spectroscopy has been conspicuously focused on soluble proteins that do not aggregate and reorient rapidly in solution. Technical advances, especially high-field magnets and small, fast computers, and methodological advances, especially multidimensional experiments utilizing pulsed irradiation at several rf frequencies, led to the development and implementation of approaches to structure determination of globular proteins in solution by the mid-1980s.^{10,11}

The immediate application of NMR to the study of membrane proteins was precluded by the difficulty of identifying resonances that could be attributed to the relatively small amounts of protein in spectra dominated by resonances from the highly abundant lipids and by the broad lines and hence, poor sensitivity and resolution obtained from proteins bound to native membranes, or multilamellar liposomes or sonicated vesicles in reconstituted systems. For these reasons the majority of the early NMR studies of membrane systems was

devoted to dynamics and organization of the lipids in bilayers, and to some extent the influence of proteins and peptides on the properties of the lipids. Nevertheless, the results of NMR experiments, especially in combination with those from contemporary ESR experiments, strongly influenced the understanding of biological membranes as dynamic entities. The NMR studies gave a picture of protein–lipid interaction where the proteins generally have a disordering effect on the membrane lipids; there is little evidence of selectivity in the interaction between proteins and lipids, with the exception of some charged species; and there is a fast exchange between protein-associated and bulk lipid, on the NMR timescale. There are a number of thorough review articles on these subjects.^{12,13}

A substantial amount of the early research on membranes was devoted to conformational studies of small membrane active polypeptide antibiotics and their interactions with phospholipids. Certain such peptides are known to induce cation permeation across cells and artificial membranes, and to form lipid soluble complexes. Early NMR studies of peptides such as alamethicin and gramicidin^{14,15} set the stage for later detailed investigations of peptide ion channels and their interaction with membranes.

The initial studies of native and reconstituted membranes demonstrated that high-resolution NMR spectra suitable for detailed structural analysis of membrane proteins could not be readily obtained.¹⁶ Sonicated vesicle samples have the advantage of being bilayers, albeit highly curved, and sealed chambers suitable for transport studies. Although spectra obtained from lipids in sonicated vesicles are considerably narrower than those in multilamellar bilayers, the overall correlation time (approximately 10^{-6} s) of the vesicles is extremely inconvenient. This means that any resonances from protein, or other molecular constituents immobilized within the vesicle are very broad because of efficient relaxation.¹⁷ These resonances do not respond to solid state NMR procedures because their breadth is due to relaxation rather than powder pattern characteristics. Therefore there have been very few ^1H or ^{13}C NMR studies of proteins in vesicles. However, some results have been obtained with ^{19}F -labeled proteins, since the number of resonances is greatly reduced and there is no interference from lipid resonances. For example, the motional properties of the M13 major coat protein, fluorinated at its two tyrosyl residues, have been examined in this manner.^{18,19} The filamentous bacteriophage coat proteins have turned out to be very valuable model systems for many types of NMR study of membrane proteins.

In 1968, Kamat and Chapman²⁰ showed that the resolution and sensitivity of ^1H NMR spectra could be substantially improved by solubilizing native membranes in lysolipid or detergent micelles. Around 1979, the first high-resolution NMR studies of membrane associated peptides in small perdeuterated micelles were reported.^{21,22} The relatively well-resolved spectra, and the observation of homonuclear NOEs in well-behaved and stable samples set the stage for many fruitful multidimensional solution NMR studies of membrane associated peptides and proteins.

3 APPLICATIONS TO MEMBRANE PROTEINS IN MICELLES

Multidimensional solution NMR methods can be applied to peptides and proteins in micelles because the reorientation

of the protein–micelle complex in solution is rapid enough to average the spectral parameters from the various nuclear spin interactions to their isotropic values. This enables the indirect effects of their fluctuations, as monitored by relaxation phenomena, to describe local dynamics as well as provide spatial information in the form of relative proximities. However, the methods of solution NMR spectroscopy are somewhat limited, at least compared with what can be done with well-behaved globular proteins in solution, by the broad linewidths and efficient spin diffusion that accompany the relatively slow reorientation of protein–micelle complexes in solution. These limitations can be minimized with careful sample preparation, especially through specific, selective, and uniform isotopic labeling of the protein, and through careful preparation of the micelles by ensuring sufficient detergent and salt concentrations to form uniform, small micelles.²³ Some membrane proteins are soluble in organic solvents or mixed aqueous solvents without lipids, and these preparations have been used in NMR studies. While well-resolved protein resonances can be observed in many cases, there is always considerable concern about the status of the protein in these solvents, especially in the popular trifluoroethanol because of its helix forming propensity. However, as the methods for studying proteins in micelles improve, there is less need to rely on solubilizing membrane proteins in organic solvents.

Protein structure determination by multidimensional NMR spectroscopy is straightforward for relatively small globular proteins in solution, especially when uniformly ^{15}N and ^{13}C labeled samples are available. There are several basic steps in protein structure determination, as widely utilized with globular proteins in aqueous solution, including: the resolution and assignment of backbone and side-chain resonances based on through-bond and through-space interactions observed in multidimensional NMR spectra; the measurement of many homonuclear ^1H – ^1H NOEs among the assigned resonances, supplementing these short range distances with other structural constraints including spin–spin coupling constants; the interpretation of all structural constraints in terms of secondary structure; and the generation of a family of three-dimensional protein structures using distance geometry, molecular dynamics, and other calculations.

Melittin has been studied extensively by NMR spectroscopy after its initial use as an example to show the feasibility of micelle samples.^{24,25} This 26-residue peptide disrupts membranes. Solution NMR studies of melittin in detergent micelles show that the amino terminal and carboxyl terminal regions are α -helical and separated by a kink. The NMR data from melittin have been subjected to considerable refinement, and provide a model for other amphipathic helical peptides that interact with membranes. The bombolitins are another class of peptides isolated from the venom of bees, whose functions include the lysis of erythrocytes and liposomes. The structures of bombolitin I and III have been investigated by ^1H NMR both in sodium dodecyl sulfate (SDS) micelles and in aqueous solution.²⁶ In micelles the presence of strong $\text{NH}(i)$ – $\text{NH}(i+1)$ NOEs over the full range of the molecules is indicative of helical structures. In water, bombolitin I lacks any observable secondary structure, while bombolitin III adopts a highly helical structure which is believed to arise from extensive peptide aggregation.

Membrane modifying channel-forming peptides of fungal origin, that are rich in hydrophobic amino acids including α -aminoisobutyric acid (Aib), have been the focus of many NMR investigations. Alamethicin is a 20 amino acid peptide known to induce voltage gated conductance in bilayers. This peptide has been studied extensively by solution NMR, both in organic solvents and, more definitively, in SDS micelles.²⁷ Interproton distances obtained from the NOE data suggest a structure for alamethicin where the amino terminus is predominantly α -helical while the carboxyl terminus is less regular and more flexible.

δ -Hemolysin is another 26 residue peptide that interacts with membranes. NMR studies of the peptide in micelles indicate that it forms an extended helix.²⁸ Typical of many membrane bound amphipathic helical peptides, δ -hemolysin gives a quite well-resolved one-dimensional ^1H NMR spectrum, with some limitations in the two-dimensional spectrum, resulting from the broad resonance linewidths and efficient spin diffusion. The 32 residue polypeptide hormone calcitonin was characterized in SDS micelles and found to have an amphipathic helix running into the amino terminal disulfide bridged loop.²⁹

The major functional channels in membranes, such as the nicotinic acetylcholine receptor and cation channels, are large oligomeric proteins. Structural studies of these proteins are limited by their overall size and the difficulty in crystallizing them. A promising approach to their analysis is to synthesize and study peptide sequences corresponding to segments of the proteins. We have studied the peptide M2 selected from the δ subunit of the torpedo acetylcholine receptor, because homology and model studies suggest that this sequence-specific motif is responsible for specific functions in the channel activity of the receptor and the 23 residue M2 δ peptide forms channels by self-association when added to membranes. Solution NMR experiments demonstrate that there is substantial helical secondary structure in the M2 δ peptide in micelles.³⁰

Many membrane interactive peptides have antibiotic activities. Cecropin A, a 37 residue peptide found in *Hyalophora cecropia* and other insects, is part of their defense mechanism against bacteria. NMR studies show that this peptide is essentially a random coil in aqueous solution. This peptide has also been studied in hexafluoroisopropyl alcohol solutions by NMR spectroscopy.^{31,32} Interproton distance restraints determined by nuclear Overhauser enhancement measurements and distance restraints hydrogen bonds were used as a basis for three-dimensional structure determination by simulated annealing. The resulting converged structures indicate that there are two α -helical regions extending from residues 5–21 and 24–37. Magainins are a family of 21–26 residue peptides that protect frogs from infections, even after severe injury, with a broad spectrum of antibacterial and antifungal activities. These peptides interact strongly with bacterial and model membranes. Their antibiotic activity appears to be associated with the disruption of the electrochemical ionic gradient across cell membranes. Multidimensional solution NMR spectra, as shown in Figure 2, indicate that magainins are unstructured in aqueous solution, but completely α -helical in detergent micelles³³ and trifluoroethanol/water solutions.³⁴

Adenosine 5'-triphosphate (ATP) synthase consists of two main components; the water soluble complex F_1 , and the membrane-bound complex F_0 . The latter, in turn, consists of three subunits (a, b and c), all of which are needed

Figure 2 Amide region of two-dimensional $^1\text{H}/^1\text{H}$ NOE spectrum of magainin-2 in micelles

for the maintenance of proton pumping. Subunit c is the smallest (79 amino acids) and most abundant subunit. The structure of subunit c dissolved in mixed organic solvents has been investigated by multidimensional solution NMR spectroscopy. The secondary structure was determined from a combination of homonuclear NOE connectivities, and coupling constant measurements. The protein consists of two long and predominantly helical segments separated by a mobile, unstructured, eight residue stretch. The amino and carboxyl termini are close together, such that the molecule is folded in a hairpin arrangement.^{35–37}

Bacteriorhodopsin, the principal component of the outer membrane of *Halobacterium halobium*, where it serves as a light-driven proton pump, is one of the most intensively studied membrane proteins. It consists of 248 amino acids and its structure is dominated by seven transmembrane hydrophobic helices. The protein binds a retinal chromophore to absorb light and translocate protons across the membrane. Solution NMR spectroscopy has been useful in characterizing the structure of bacteriorhodopsin. Fragments corresponding to several of the transmembrane helical sections have been obtained by proteolytic cleavage or peptide synthesis, and have been studied in both organic solvents and detergent micelles. For example, the 34–65 fragment peptide, corresponding to the membrane spanning segment B, was investigated in SDS micelles where it was found to adopt a right-handed helix from residues 41 to 62 with a kink at residue 50, and a disordered amino terminus from residues 34 to 40.³⁸ The longer 163–231 fragment peptide, corresponding to the transmembrane segments F and G, was also investigated in a similar fashion and found to contain extensive regions of right-handed helix and a flexible amino terminus.³⁹

4 SOLID STATE NMR SPECTROSCOPY OF MEMBRANE PROTEINS IN LIPID BILAYERS

Polypeptides that are strongly associated with phospholipids are well suited for solid state NMR spectroscopy,^{30,40,41} because their structured regions are essentially completely

immobilized on the timescales defined by the spectral ranges (10^3 – 10^6 Hz) of the chemical shift, dipolar, and quadrupolar spin-interactions of the nuclei present in proteins. This immobilization preserves the anisotropic characteristics of the nuclear spin interactions averaged out by the rapid isotropic reorientation that occurs in solution, including proteins in micelles. Since it is possible to prepare both oriented and unoriented samples of proteins in fully hydrated phospholipid bilayers, many different parameters can be resolved and measured from single line and powder pattern spectra.

In solid state NMR spectroscopy rf irradiation supplemented by mechanical sample spinning or orientation replace molecular motions as line-narrowing mechanisms. Not only do solid state NMR methods give spectra with high-resolution and sensitivity, they also enable measurements of distance and orientational parameters. There are two complementary methods for protein structure determination by solid state NMR spectroscopy. In one approach, orientational constraints for bonds and chemical groups are derived from spectral parameters observed in samples of peptides and proteins embedded in lipid bilayers oriented between glass plates.⁴² In the other approach, unoriented or powder samples examined in the presence of magic angle sample spinning employ procedures to preserve the dipolar couplings so they can be used for distance measurements.^{43,44}

Very favorable spectroscopic properties are associated with uniaxially oriented samples where the axis of molecular orientation lies parallel to the direction of the applied magnetic field.⁴⁵ Spectra from these samples consist of single line resonances (or multiplets) rather than powder patterns from each isotopically labeled site. Since the observed resonance frequencies (or splittings) are directly related to the orientations of individual atoms or bonds relative to the axis defined by the direction of the applied magnetic field, spectroscopic measurements on oriented samples provide the basis for protein structure determination. The nuclear spin interactions provide spectral parameters that vary as a function of the angle between a bond (or a chemical group) and the direction of the applied magnetic field.

High-resolution structures can be determined with two or more spectroscopic measurements for each structural element, such as a peptide plane or indole ring, since each orientation can be related to a common axis defined by the direction of macroscopic molecular orientation and the applied magnetic field.⁴⁶ The orientational constraints together with the established covalent geometry of the molecule are sufficient to define the complete three-dimensional structure. Limited but worthwhile orientational information can be derived from single spectroscopic measurements on oriented samples.⁴² Once the secondary structure of a polypeptide segment is established, for example from multidimensional solution NMR experiments on samples in micelles, a single spectral parameter is often sufficient to establish the orientation of a helix relative to the plane of the bilayer, which is especially valuable in studies of membrane proteins where helices are often the dominant secondary structural feature.

The structure of a protein can be determined from the measurement of many short-range distances. Distances can be measured quantitatively between pairs of nuclei with solid state NMR experiments. Magic angle sample spinning enables high resolution spectra to be obtained from unoriented samples; however, since the spinning averages out both the

unwanted broadening from the chemical shift anisotropy as well as the dipolar couplings essential for the measurements, it is necessary to cancel out selectively the effects of the spinning on the dipolar interactions. Different experimental approaches are used depending on whether homo- or heteronuclear dipole–dipole couplings are the source of distance information. This application of solid state NMR spectroscopy is rapidly increasing in popularity for structural studies of a variety of biopolymers, including peptides and proteins in lipid bilayers.⁴⁷

It is possible to arrange for heteronuclear dipole–dipole interactions to be present at locations throughout polypeptides by isotopic labeling, enabling distance measurements between specific sites of interest. Rotational echo double-resonance (REDOR) NMR spectroscopy is a general method for measuring internuclear distances between two different nuclei that utilizes rf pulses at the resonance frequency for one of the types of coupled spins to interfere with the averaging of the dipole–dipole interactions.⁴³ Rotational resonance spectroscopy is also used with magic angle sample spinning to measure weak dipole–dipole couplings,⁴⁴ although, unlike REDOR, it is a homonuclear method measuring distances between the same kind of nuclei. The method depends on special effects that occur when the spinning frequency is an integral multiple of the chemical shift difference between the two labeled sites.

Helical peptides are of interest in studies of membrane proteins because they serve as independent structural or functional entities of monomers, oligomers, or domains of larger proteins associated with membranes. Helical peptides, whether hydrophobic or amphipathic, have been found to adopt either transmembrane or in-plane orientations in bilayers, and solid state NMR experiments on oriented samples are adept at differentiating between these two situations. Once the secondary structure is established as helical, then a single solid state NMR measurement is generally sufficient to determine the orientation of the helix in the bilayer. Both qualitative and quantitative analyses of the orientational parameters have given consistent results in determining transmembrane and in-plane orientations of helices. The ^{15}N chemical shift for labeled amide sites is particularly useful for distinguishing between transmembrane and in-plane orientations of helices because of the convenient orientation of the chemical shift tensor in the molecular frame.⁴² A conformation with the N–H bond approximately parallel to the field, which occurs for a transmembrane helix in oriented bilayers, has a ^{15}N chemical shift with a frequency near $\sigma_{\parallel}$, while a conformation with the N–H bond approximately perpendicular to the field, which occurs for an in-plane helix in oriented bilayers, has a ^{15}N chemical shift with a frequency near $\sigma_{\perp}$. These frequencies are separated by the full breadth of the chemical shift anisotropy powder pattern illustrated with the spectra in Figure 3. For example, the spectrum in Figure 3(c) is from a single ^{15}N labeled amide site in a 23 residue peptide with the sequence corresponding to the M2 helical segment of the δ subunit of the acetylcholine receptor, which has been shown to be helical.³⁰ The M2 peptide is shown to have a transmembrane orientation (Figure 4) because its ^{15}N resonance frequency is near the low frequency (high field) ($\sigma_{\parallel}$) edge of the powder pattern. This orientation is consistent with the model for its functioning as a channel by oligomerization within the bilayers.

Figure 3 (a,b) Experimental solid state ^{15}N NMR spectra of 23 residue amphipathic peptides in oriented bilayers. (a) ^{15}N Ala-labeled magainin-2. (b) ^{15}N Ala-12-labeled M2 δ peptide. (c) Simulation of the powder pattern for an immobile ^{15}N amide site

Figure 4 Schematic drawing of in-plane (magainin-2) and transmembrane (M2 δ) orientations of 23-residue amphipathic helical peptides in lipid bilayers. The helical backbones are represented by their 22 peptide bond planes, whereas the white boxes indicate the extending side chains

Contrast the position of the ^{15}N resonance from the M2 transmembrane peptide in Figure 3(b) to that from the magainin-2 peptide in Figure 3(a), which has a ^{15}N resonance frequency near the high frequency ($\sigma_{\perp}$) edge of the powder pattern. This large 170 ppm difference in resonance frequencies is due solely to the difference in orientations of the peptides in the bilayer. Magainin antibiotic peptides from frog skin have been investigated by solid state NMR spectroscopy in lipid bilayers. Their secondary structure has been demonstrated to be a helical by a variety of methods, including solid state NMR spectroscopy.⁴⁸ Spectra, such as that shown in Figure 3(b), from many labeled sites indicate that these peptides are oriented through their entire length in the plane of the bilayers, as shown in Figure 4. In other experiments the heteronuclear dipole–dipole splittings associated with the labeled sites have been measured, providing a second spectral parameter for each site. This enabled the structural determination of four contiguous residues of magainin-2 based only on solid state NMR experiments of oriented samples.

The α -helical secondary structure is in complete agreement with that determined by a variety of other methods, including multidimensional solution NMR spectroscopy in micelles. However, solid state NMR spectroscopy of oriented bilayer samples is unique in being able to determine the in-plane orientation of the helix in the bilayer.

Rotational resonance spectroscopy has been used to measure the distances between ^{13}C labeled sites in peptides with sequences corresponding to the transmembrane domain of glycophorin A protein in lipid bilayers.⁴⁹ These measurements indicate a helical geometry throughout the peptide, with some evidence of unraveling of the helix near the membrane surface. Measurements have also been made of the distances between sites on the lipids and on the peptides, indicating the feasibility for using these methods to characterize fundamental peptide–membrane interactions.⁵⁰

Gramicidin A is a linear polypeptide of 15 amino acid residues having alternating D and L stereochemistry. As an amino terminus to amino terminus dimer, gramicidin forms a monovalent cation selective channel across lipid bilayers and natural membranes. The channel conformation is a β -strand that forms a helix with 6.3 residues per turn. Solid state NMR spectra of oriented samples provide very high resolution constraints, making it possible to define each peptide plane orientation with respect to the magnetic field. By combining data from adjacent planes and the tetrahedral geometry of the C- α atom, the $\Phi\Psi$ torsion angles can be determined.⁵¹ Considerable effort has been devoted to a characterization of the gramicidin side-chain conformation and dynamics,^{52,53} in particular to the four indole groups per monomer.^{54,55} The orientation for each indole ring with respect to the channel axis and bilayer normal has been determined. This information contributes to models for the roles of indoles in channel conductance. REDOR has been used to measure the dipolar coupling between the Gly-2 ^{13}C -1 carbon and Ala-3 ^{15}N amide nitrogen atom in a sample of gramicidin where the peptide was in lipid bilayers.⁵⁶ This effective coupling was used to determine the orientation of this bond with respect to the bilayer normal. A significant feature of these measurements is that they give the magnitude and sign of the dipolar coupling, enabling the angle to be reduced to a single value and its supplement. This information about the Gly-2-Ala-3 ^{13}C – ^{15}N peptide bond angle was consistent with the data obtained from orientational constraints, showing that gramicidin is a right-handed, single-stranded β -helical dimer in lipid bilayers.

Bacteriorhodopsin has been used in the development of many methods, including solid state NMR spectroscopy,⁵⁷ for probing the structures of membrane proteins. The configuration of the single molecule of retinal bound to bacteriorhodopsin and involved in its mechanism of action is the key to understanding its chemical mechanism. Watts and co-workers have labeled both ring⁵⁸ and individual methyl groups⁵⁹ along the retinal moiety with ^2H . From oriented preparations and the resulting orientational constraints a detailed picture of the bound chromophore conformation has been established. These results add to the large number of prior studies of the retinal with rotational resonance methods. Rotational resonance methods have also been used to measure distances between sites on the retinal chromophore and protein residues.⁶⁰ By utilizing the ^{13}C -labeled retinals and ^{13}C - ϵ lysine labeled bacteriorhodopsin, it was possible to take advantage of the

unique chemical shift of the C- ϵ atom of the lysine involved in the Schiff base.

5 NMR STUDIES OF THE MEMBRANE BOUND FORM OF FILAMENTOUS BACTERIOPHAGE COAT PROTEIN

The membrane bound filamentous bacteriophage coat protein is a small, but typical membrane protein with both amphipathic and hydrophobic helices. It has been the subject of extensive NMR studies in both micelle and bilayer samples and provides an excellent system to illustrate what can be done by combining results from both of these methods. fd is a filamentous bacteriophage that infects *Escherichia coli* and has approximately 2700 copies of a 50 residue major coat protein surrounding its DNA. The viral coat protein is synthesized with an amino terminal signal sequence which directs it to the bacterial inner membrane before being removed by cleavage with leader peptidase. The coat protein becomes the most abundant membrane in infected cells, and then subunits assemble to form the outer coat of the virus particles as they are extruded through the membrane.

fd coat protein in micelles was the first protein shown to have such heterogeneous backbone dynamics that resonances from mobile residues could be clearly distinguished from the rigid residues on the basis of multiple relaxation parameters. Initially, about eight of the backbone C- α resonances were observed to have much narrower linewidths, longer T_1 values, and larger heteronuclear NOEs than the rest of the C- α resonances in natural abundance ^{13}C NMR spectra of fd coat protein in SDS micelles.⁶¹ The presence of mobile amide backbone sites near the amino and carboxyl termini in the membrane bound form of fd coat protein was also shown with ^{15}N -labeled samples in micelles by the observation of large negative heteronuclear $^1\text{H}/^{15}\text{N}$ NOEs and in bilayers with the observation of narrow isotropic resonance intensity in ^{15}N solid state NMR spectra.⁸ The observation of narrow ^{13}C resonance linewidths for some carbonyl sites confirmed that the coat protein had mobile backbone sites in micelle samples.⁶² Additional evidence for mobile residues comes from labeled side-chain sites with the observation of isotropic resonance intensity in ^2H solid state NMR spectra of samples in bilayers⁶³ and with the analysis of the relaxation properties of $^{13}\text{CH}_3$ labeled alanine residues.⁶⁴

Additional evidence concerning protein backbone dynamics comes from the kinetics of hydrogen exchange at amide sites; however, these data are more difficult to interpret directly in terms of protein structure and fluctuations. There are substantial qualitative differences in the exchange rates of amides in different parts of the protein.^{61,65} The exchange rates of individual amide sites throughout the protein have been measured;⁶⁶ the finding was that residues 28 and 45 undergo very slow exchange, while residues 7 and 20 exchange more rapidly, although not nearly as fast as for unstructured solvent exposed sites.

The determination of the secondary structure of fd coat protein in SDS micelles utilizes multidimensional NMR spectroscopy.^{66–68} The majority of the sequential assignments of the amide resonances were made using homonuclear ^1H NOE data from two- and three-dimensional NOE/HMQC

Figure 5 Three-dimensional ($^1\text{H}/^{15}\text{N}$ HMQC/ $^1\text{H}/^1\text{H}$ NOE) solution spectrum of uniformly ^{15}N labeled fd coat protein in SDS micelles in solution

experiments as shown in Figure 5, supplemented with information from TOCSY/HMQC experiments, and spectra of selectively ^{15}N -labeled samples.⁶⁷ All the NOE data are consistent with extensive helical secondary structure in the protein; in particular, NOEs are observed between NH-NH($i, i + 1$), NH-C- αH ($i, i + 1$), NH-C- βH ($i, i + 1$), NH-C- αH ($i, i + 3$), and NH-C- αH ($i, i + 4$) for many residues determined to have helical secondary structure. The $^1\text{H}/^1\text{H}$ strips in Figure 6 at ^{15}N chemical shifts corresponding to S13, L14, and Q15 show the presence of NOEs between resonances from hydrogen atoms on adjacent amide nitrogens, and α - and β -carbon atoms; these residues are part of an amphipathic helix that lies in the plane of the lipid bilayer. K40, L41, and F42 also exhibit these characteristic NOEs and are a part of

Figure 6 Strips taken from the three-dimensional spectrum shown in Figure 5

Figure 7 Solid state ^{15}N NMR spectra of uniformly and selectively ^{15}N -labeled fd coat protein in phospholipid bilayer samples. (a) Uniformly ^{15}N -labeled fd coat protein in bilayers oriented between glass plates. (b) Uniformly ^{15}N -labeled fd coat protein in unoriented bilayers. (c) Selectively ^{15}N -labeled fd coat protein in bilayers oriented between glass plates. (d) Selectively ^{15}N -labeled fd coat protein in unoriented bilayers. (e) Selectively ^{15}N -labeled fd coat protein in bilayers oriented between glass plates. (f) Selectively ^{15}N -labeled fd coat protein in unoriented bilayers

the hydrophobic transmembrane helix. The numerous NOEs observed for residues 13–15 and 40–42 are between $\text{NH}-\text{C}-\alpha\text{H}(i, i + 3)$ and $\text{NH}-\text{C}-\alpha\text{H}(i, i + 4)$ sites, and strongly support the presence of helical secondary structure for these residues. The absence of NOEs for residues 1–5 at the amino terminus of the coat protein indicates that these residues do not participate in stable secondary structure, and the strip from the NOE/HMQC experiment (corresponding to G3 in Figure 8 below) has no NOEs to any other residue. Residues 1–5 are highly mobile, as seen in relaxation data of the coat protein in micelle samples.⁸

The ^{15}N chemical shift powder patterns from unoriented samples of uniformly [Figure 7(b)] and selectively ^{15}N -labeled fd coat protein in lipid bilayers [Figure 7(d)] establish that the membrane bound form of the protein has both mobile and rigid backbone sites. The amide groups of both L14 and L41 are immobile in membrane bilayers because the powder pattern spectrum in Figure 7(d) shows little evidence of motional averaging. However, the spectrum in Figure 7(b) from the uniformly ^{15}N -labeled sample has substantial isotropic intensity from the mobile amino and carboxyl terminal residues.

^{15}N solid state NMR spectra of selectively ^{15}N -labeled coat proteins in unoriented phospholipid bilayers and in oriented phospholipid bilayers are shown in Figure 7(d) and (c), respectively. The comparison of these spectra shows the effect of sample orientation; the two ^{15}N resonances go from a broad, characteristically shaped powder pattern to narrow, single lines with frequencies determined by the orientation of the peptide planes with respect to the direction of the magnetic field. Comparison of the spectra in Figure 7(a) and (b) also shows the effect of sample orientation, although at lower resolution because of multiple overlapping resonances in the uniformly ^{15}N -labeled samples. However, the resonance bands occur at the positions expected for transmembrane and in-plane helices. Since the secondary structure for the two leucine residues is established as helix by the NOE data in Figure 6, the resonance frequency of each nitrogen site can be used to establish the orientations of the helices relative to the plane of the bilayer. The spectrum of ^{15}N -labeled

Figure 8 Model of the membrane-bound form of fd coat protein. The amphipathic helix is parallel to the plane of the bilayer, the hydrophobic helix spans the membrane, and the terminal residues and bend are mobile

coat protein in oriented bilayers [Figure 7(c)] has one line with a resonance frequency near $\sigma_{\parallel}$ and a second line with a resonance frequency near $\sigma_{\perp}$, indicating that the hydrophobic helix spans the bilayer because the N–H bond of one of the leucine residues is parallel to the direction of orientation and that the amphipathic helix is in the plane of the bilayer because the N–H bond of the other leucine residue is perpendicular to the direction of orientation.

Figure 8 summarizes the results of the NMR experiments.⁶⁷ The structure and dynamics of the membrane bound form of fd coat protein were determined by combining results from solid state NMR experiments of the coat protein in bilayers with solution NMR results of the coat protein in micelles. The secondary structure of the protein is almost entirely helical, based on the observation of NOEs among all amide resonances from adjacent residues 7–50 and the NOEs between hydrogen atoms on the nitrogen amide and the α -carbon atoms three and four residues away. The orientation of the helical segments were determined by solid state NMR experiments that showed residues in the amphipathic helix lying parallel to the plane of the bilayer and residues in the hydrophobic helix spanning the bilayer. Tyr-21 is located between the two helices; it is structured on short timescales but shows evidence of mobility on the slower solid state NMR timescale, as shown in Figure 7(f). The presence of strong $\text{NH}-\text{NH}(i, i + 1)$ and $\text{NH}-\text{C}-\alpha\text{H}(i, i + 2)$ NOEs, and the mobility of Y21 on slow timescales suggest that it participates in a turn that connects the two helical regions. Residues 1–5 at the amino terminus of the protein are highly mobile based on a variety of relaxation data in micelle samples and motional averaging of lineshapes in bilayer samples. Residues at the carboxyl terminus are also mobile in both bilayer and micelle samples; however, the observation of homonuclear NOEs indicates that helical secondary structure extends through to the carboxyl terminal on some timescales.

The features of the model of the membrane bound form of fd coat protein are similar to those found for the membrane bound form of Pf1 coat protein,⁶⁹ in spite of the absence of sequence homology between these proteins. The structure and dynamics

of the membrane bound forms of both fd and Pf1 coat proteins were characterized by combining the results of solution and solid state NMR spectroscopies. Both proteins consist of helical secondary structure intermixed with mobile termini and loop regions. The helical regions in fd and Pf1 coat protein consist of two segments, with hydrophobic residues forming a transmembrane helix and amphipathic residues forming a helix parallel to the bilayer plane. The two proteins differ most in the extent of mobility of the segment connecting the two helices. The connecting loop residues in Pf1 are highly mobile on both slow (10^{-4} s) and fast (10^{-9} s) timescales with an absence of homonuclear ^1H NOE cross peaks involving the amide resonances for these residues. In contrast, fd coat protein has homonuclear NOE cross peaks throughout the sequence, including the residues involved in the turn connecting the two helices; there is evidence of limited motional averaging for Tyr-21.

6 PROSPECTS FOR NMR STUDIES OF MEMBRANE PROTEINS

Structural studies devoted to membrane proteins seek to determine their three-dimensional structure and dynamics, with the ultimate aim of integrating these properties into models for their mechanism of action within the natural environment of the biological membrane. Since the structure and function of membrane proteins are intimately related to their hydrophobic membrane environment, serious investigations of these species must, at some stage, focus on the entire supramolecular assembly. NMR spectroscopy has proved itself to be a well suited and sufficiently versatile technique for this purpose, with the micelle and the bilayer samples providing excellent supramolecular model systems for multidimensional NMR solution and solid state NMR studies, respectively. Thus, considering the already large impact of NMR spectroscopy in the membrane protein field, there is good reason to be optimistic that, as the sample preparation and spectroscopic methods are improved, NMR spectroscopy will become generally applicable to the study of membrane proteins.

The development of multidimensional solution NMR spectroscopy of membrane proteins in micelles will be similar to that for larger globular proteins, since the limiting factor, the rotational correlation time, is the same in both cases. The solid state NMR methods that utilize uniaxially oriented samples or implement magic angle sample spinning to achieve resolution, provide measurements of angles and distances between bonds and chemical groups which can be interpreted in terms of structures. The former method has the added advantage of providing details about the orientation of the protein structural elements with respect to the plane of the lipid bilayer. Thus, by using macroscopically and uniaxially oriented membrane samples it becomes possible to distinguish between the case where the protein is membrane spanning and that where the protein associates only superficially with the membrane, or, yet again, where the protein interacts with the bilayer in a wedge-like manner. This is important for understanding the functions of membrane proteins, since they interact asymmetrically with the membrane, imparting different properties to its inner and outer leaflets. The situation is a very different from the more or less isotropic environment of the cell cytoplasm and periplasm

occupied by globular proteins. As a result, NMR spectroscopy has the potential of opening up an entire area of structural biology by providing an added dimension for membrane protein studies.

1 INTRODUCTION

Metallothioneins (MTs) are a unique group of low molecular weight, cysteine-rich proteins that bind both essential (e.g. copper and zinc) and nonessential (e.g. cadmium and mercury) metals.¹ Since their discovery in 1957 in equine kidney cortex, MTs have been identified from a variety of mammals, birds, fish, invertebrates, plants, eukaryotic microorganisms, and some prokaryotes. The widespread occurrence of MTs in nature suggests that they serve an important biological function, although their exact role has yet to be defined. Since MT gene transcription is inducible by the same heavy metals that are subsequently found bound to the protein, MTs are thought to act as heavy metal detoxifying agents by sequestering such toxic metals as cadmium, mercury, and a variety of other heavy metal ions under conditions of stressful metal overloads. It is also likely that MTs participate in essential zinc and copper metabolism or homeostasis, perhaps serving in a storage or transport capacity. Various aspects of the MT chemistry, biochemistry, molecular biology, physiology, and toxicology have been reviewed.^{2,3}

Metallothioneins are subdivided into three classes: class I comprises MTs of mammalian and other origin with related primary structure, class II includes MTs unrelated to the mammalian forms, and class III consists of atypical polypeptides with γ -glutamylcysteine residues (Figure 1). Of the 61 amino acid residues in mammalian MTs, there are 20 cysteines that serve as ligands to the 7 g-atoms mol⁻¹ of divalent metal ion bound by the protein. In addition, MTs contain several serines and lysines in highly conserved positions in the sequence, whereas aromatic residues and His are completely absent.

These highly unusual compositional features of MTs consisting of multiple metals bound presumably exclusively to

cysteine sulfhydryl groups plagued early attempts using spectrophotometric and complexometric titration data to characterize the tertiary structure of these proteins. On the basis of these studies, the prevailing model until the late 1970s consisted of multiple, separate metal-binding sites as depicted schematically in Figure 2. These very features, coupled with the fact that this was the first, and until this day the only, naturally occurring cadmium-containing protein, attracted our interest to this protein in our early efforts to establish the usefulness of ¹¹³Cd NMR methods to probe the structure of the ¹¹³Cd-substituted metal-binding site(s) in a variety of metalloproteins.⁴ Fortunately, both our intuition and the spin physics of the spin- $\frac{1}{2}$ ¹¹³Cd²⁺ ion cooperated, and with this technique we were able to resolve each of the individual metal-binding sites in this protein, which laid the foundation for studies that ultimately led to the elucidation of this protein's three-dimensional (3D) structure (see below).

2 CADMIUM-113 NMR

Numerous investigators have employed ¹¹³Cd NMR in studying the properties of a variety of metalloproteins and biological events in which the native Zn²⁺, Ca²⁺, Mg²⁺, Mn²⁺, Cu²⁺, or Cd²⁺ ions were replaced by ¹¹³Cd²⁺.⁴⁻⁷ Some of the chemical and magnetic properties of the ¹¹³Cd²⁺ ion to which this approach owes its success are the following:

1. The coordination of Cd²⁺ is quite similar to that of Zn²⁺ and Ca²⁺, and Cd²⁺ and Ca²⁺ have similar ionic radii of 0.97 and 0.99 Å, respectively.
2. Cd²⁺ has been substituted for the native Zn²⁺ in a variety of metalloenzymes and deoxyribonucleic acid (DNA)-binding proteins. In the former, catalytic efficiency and specificity are frequently altered but usually not abolished, whereas in the latter, DNA binding is retained.
3. Cadmium-113 chemical shifts are extremely sensitive to the nature, number, and geometric arrangement of the ligands within the coordination sphere. This sensitivity is reflected in the chemical shift range of almost 900 ppm observed for the resonances from ¹¹³Cd²⁺-substituted metalloproteins. This property is useful not only in helping to identify the ligands at a particular metal-binding site, but also because it virtually guarantees the resolution of individual ¹¹³Cd resonances in systems containing multiple metal ions as is the case in MTs.

2.1 Sensitivity

There are two naturally occurring, diamagnetic, spin- $\frac{1}{2}$ cadmium isotopes, ¹¹³Cd and ¹¹¹Cd, which are present at 12.3% and 12.7% natural abundance, respectively. Despite the fact that the two isotopes have virtually identical NMR properties, ¹¹³Cd has been used almost exclusively for biological NMR studies. The inherent sensitivity of the ¹¹³Cd nucleus is about 1% that of ¹H and 70% that of ¹³C. At natural abundance levels, the sensitivity of ¹¹³Cd is 7.6 times that of ¹³C which is still insufficient for most biological Cd NMR studies. Instead, 96% isotopically enriched ¹¹³Cd is employed, affording an 8-fold enhancement in sensitivity. Reasonable spectra may be obtained from approximately 2 mL of a 1 mM sample of a Cd-substituted metalloprotein in 5–10 h of data accumulation at intermediate/high fields.

Figure 1 Amino acid sequences of representative MTs. Open positions denote deletions introduced for optimal alignment of class I MTs; numeration refers to the sequence determined for human MT-2

Studies of Cd^{2+} complexes in aqueous solutions show a consistent correlation between the chemical shift and the identity of the ligands to the metal ion. Oxygen ligands provide the greatest shielding, nitrogen and halide ligands are relatively deshielding, and sulfur ligands are the most deshielding.⁴⁻⁷ Ideally, one would like to be able to interpret ^{113}Cd chemical shifts for proteins in terms of the identity, number, and geometric arrangement of the ligands at the binding site. Unfortunately, two obstacles have so far restricted the establishment of such a detailed structure-chemical shift correlation. The first problem stems from the facile chemical exchange that usually exists between hydrated cadmium complexes in aqueous solution. The consequence of this is that the solution ^{113}Cd chemical shift of a cadmium compound of known structure will not necessarily be indicative of that complex alone, but will instead be a weighted average of the chemical shifts of multiple species in rapid equilibrium. This difficulty may be overcome either by bringing the labile inorganic system into the slow exchange regime by the use of supercooled aqueous solutions, or by recording the chemical

Thus, although we have not yet achieved the desired level of quantification, the existing qualitative structure–chemical shift correlation is sufficiently well established to permit its use for tentative assignments of metal ligand types in biological systems. In every case in which ^{113}Cd chemical shift determinations have been made in proteins whose binding sites had previously been characterized by X-ray diffraction, good correspondence has been found between the observed shift and that expected on the basis of the protein–metal ligands. This is demonstrated in Figure 3, which shows a compilation of the solution ^{113}Cd chemical shifts of many $^{113}\text{Cd}^{2+}$ -substituted metalloproteins reported to date with characterized metal-binding sites(s). Resonances from cadmium bound to sites consisting exclusively of oxygen ligands are invariably found in the region of 0 to -125 ppm, those from sites containing a combination of oxygen and nitrogen ligands appear between 0 and 300 ppm, and resonances from sites containing two or more thiolate sulfur ligands are found in the highest frequency (most downfield) region between 450 and 750 ppm.

The observation of scalar coupling in the ^{113}Cd NMR resonances in biological macromolecules can provide unequivocal information about the nature of the ligands and their mode of binding. Table 1 shows the range of coupling constant values reported for nuclei of biological interest. In the case of the MTs, the observation of ^{113}Cd – ^{113}Cd two-bond couplings was instrumental in the elucidation of the two-cluster structure arrangement (see below). Similarly, identification of the heteronuclear three-bond couplings between each ^{113}Cd ion and the β protons of their cysteine ligands was indispensable in the determination of the solution tertiary structure of MT by two-dimensional (2D) NMR methods.⁹ Exploitation of the Karplus-type dependence of these couplings on the $\text{H}\beta\text{--C}\beta\text{--S--Cd}$ dihedral angle is expected to provide an even

Figure 3 Observed ^{113}Cd chemical shifts for ^{113}Cd -substituted metalloproteins. All shifts are reported relative to external 0.1 M $\text{Cd}(\text{ClO}_4)_2$. A bar indicates that a range of values have been observed for the same site under a variety of conditions or, in the case of mammalian MT, the distribution of the seven ^{113}Cd signals from the two metal clusters. The identity and number of metal ligands is also indicated. S and S* denote cysteine and methionine sulfur ligation, respectively. Table 1 Scalar Coupling Constants of ^{113}Cd with Nuclei of Biological Interest for Model Compounds and Metalloproteins in Aqueous Solution^{5, 6, 7, 10}

Coupling	1J (Hz)	2J (Hz)	3J (Hz)
$^{113}\text{Cd}-^1\text{H}$	—	50–53	0.5–80
$^{113}\text{Cd}-^{13}\text{C}$	498–1060	3–19	5–45
$^{113}\text{Cd}-^{15}\text{N}$	140–210	—	—
$^{113}\text{Cd}-^{31}\text{P}$	1200–1710	2–30	—
$^{113}\text{Cd}-^{113}\text{Cd}$	—	29–48	—

more accurate definition of the metal-binding site arrangements in future MT structure determinations by NMR.¹⁰ It is also noteworthy that, in addition to structural information, the observation of ^{113}Cd scalar coupling in MT and other metalloproteins is indicative of slow exchange of the metal(s) at the binding sites ($k_{\text{off}} \leq 10^2 \text{ s}^{-1}$).

2.4 Relaxation Properties

The spin relaxation properties of ^{113}Cd in a given system are of interest for at least two reasons. The first is a purely practical one: a working knowledge of the

spin–lattice relaxation time T_1 and the nuclear Overhauser enhancement (NOE) is essential for determining the most efficient conditions for data collection. The second reason is more fundamental: by analyzing the relaxation data in terms of appropriate theoretical models one can derive valuable information concerning motional dynamics at the metal-binding site. Unfortunately, owing to the lack of the detailed characterization of the contributions to ^{113}Cd relaxation in macromolecular systems, this potential source of information remains largely unexploited.

The important relaxation mechanisms operative for the ^{113}Cd nucleus in metalloproteins are chemical shift anisotropy (CSA) and $^{113}\text{Cd}-^1\text{H}$ dipole–dipole (DD) interactions.^{4,5,7} At magnetic fields above about 6 T, CSA is usually dominant but resonance broadening has not been as severe as to impair detection (Figure 4). Dipole–dipole relaxation is relatively inefficient since the protons on typical metal ligands are usually $\geq 3.5 \text{ \AA}$ distant, with exchangeable protons in the first hydration sphere, if present, being somewhat closer ($\approx 2.9 \text{ \AA}$). Therefore, if only DD relaxation were operative, ^{113}Cd T_1 values of metalloproteins would be excessively long. Measured ^{113}Cd T_1 values of metalloproteins range from 0.1 to 10 s,^{7,11} with those of MT being about 0.5 s at 4.7 T or about 0.1 s at 11.7 T.

Figure 4 Proton-decoupled ^{113}Cd NMR spectra at 55 MHz (a) and 110 MHz (b) of reconstituted rabbit $[^{113}\text{Cd}_7]\text{-MT-2}$. The $^{113}\text{Cd}\text{-}^{113}\text{Cd}$ splittings seen in the 55 MHz spectrum are obscured at 110 MHz by the increased linewidth due to more efficient CSA relaxation

The relative contributions of CSA and DD may be estimated from solid state ^{113}Cd spectra⁸ that yield the CSA $\Delta\sigma$, and from $^{113}\text{Cd}\{^1\text{H}\}$ NOE measurements,^{4,5} respectively, with prior knowledge or assumption(s) about correlation time(s), number of relaxing protons, and Cd–H distances. The very limited CSA data on calcium-binding proteins suggest $\Delta\sigma$ values in the 90–140 ppm range, and generally asymmetric metal-binding sites.^{6,8}

Because of the negative magnetogyric ratio of ^{113}Cd , proton decoupling can in many circumstances cause a complete disappearance of Cd signal intensity owing to the induction of a NOE close to -1 .^{4,5} Such has been observed for mammalian MT at 2.1 T.⁴ For this reason, plus the fact that $^{113}\text{Cd}\text{-}^1\text{H}$ splittings are often of smaller magnitude than the natural or exchange-broadened linewidths of the ^{113}Cd resonances, proton decoupling is rarely employed in ^{113}Cd NMR studies of metalloproteins.

2.5 Chemical Exchange

The observation of ^{113}Cd NMR resonances is frequently compromised in biological systems by the presence of chemical exchange broadening. The problem stems from the great sensitivity of ^{113}Cd chemical shifts to even minor fluctuations in the inner- or outer-sphere coordination environment. Processes that modulate the environments of protein-bound metal ions often occur at rates that are too fast to influence the NMR signals of the protein proper, but fall into the intermediate exchange regime of ^{113}Cd .

Dissociation of Cd^{2+} from most proteins would be accompanied by a chemical shift change of at least 100 ppm. Thus, only relatively large off-rates (10^4 s^{-1} or higher) would be expected to lead to significant exchange broadening of a protein-bound metal ion. The only sites likely to fall into this category are the low-affinity sites of calcium-binding proteins. A more important source of exchange modulation is that created by competition of solvent and counterion molecules for any ‘open’ metal coordination sites not occupied by protein ligands. Solvent exchange rates are known to be quite rapid and can easily

fall within the range that can create intermediate exchange ^{113}Cd broadening. Less is known about the rates of exchange of ligands contributed by the protein or dynamic changes in the metal coordination environment brought about by protein conformational changes. Both of these processes, however, are considered likely to be capable of inducing significant exchange broadening. In the event that an expected ^{113}Cd resonance remains undetectable within the limits of the conventional experimental parameters, including variations of pH, temperature, and ionic conditions, alternative methods such as the use of supercooled microemulsions or solid state NMR should be considered.^{5,8} The latter approach has been used to confirm that the solution state ^{113}Cd chemical shifts of rabbit MT are not influenced by ligand exchange rates.⁵

3 NMR STUDIES OF METALLOTHIONEINS

That the seven divalent metal ions in mammalian MTs are coordinated exclusively by the thiolate sulfurs of the protein’s 20 cysteine residues was originally inferred by the invariant amino acid sequence positions of the cysteines plus the absence of any disulfide bonds. Cadmium-113 NMR was capable of resolving all seven resonances (Figure 4) and provided the first direct proof that the metals reside in polynuclear clusters, as evidenced by the observed spin–spin splittings that arose from the two-bond $^{113}\text{Cd}\text{-}^{113}\text{Cd}$ scalar coupling.¹² In agreement with other spectroscopic results, the observed range of ^{113}Cd chemical shifts (about 600–670 ppm) supported the proposal that all metals adopt tetrahedral-like coordination to four thiolate ligands. To reconcile the stoichiometry of about three cysteines (Cys) per metal ion with tetrahedral coordination, a metal–thiolate cluster arrangement was proposed in which there is sharing of some thiolate ligands by two adjacent metal ions, and is consistent with the observed $^{113}\text{Cd}\text{-}^{113}\text{Cd}$ coupling.

In mammalian and crab MTs, the metals reside in two distinct clusters.⁴ Homonuclear ^{113}Cd decoupling studies on mammalian MTs readily allowed the separation of the resonances into two linkage groups, $\text{Cd}_4\text{Cys}_{11}$, or cluster α , and Cd_3Cys_9 or cluster β (Figure 5). This arrangement was subsequently confirmed by ^{113}Cd COSY spectroscopy¹³ (Figure 6) and independently verified by limited enzymatic proteolysis.⁵ The ^{113}Cd NMR spectrum of the isolated $\text{Cys}_{11}\text{Cd}_4$ C-terminal domain showed four resonances with chemical shifts corresponding to the four resonances of the 4-metal cluster in the intact protein. Similar homonuclear

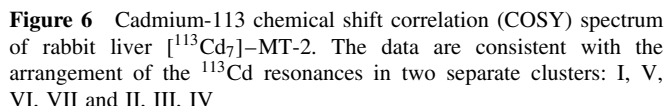

Figure 5 Structures of the 4-metal and 3-metal clusters existing in MTs

Despite binding very tightly, the metals in mammalian MTs participate in surprisingly facile ligand exchange reactions that induce rapid intermolecular metal transfer between β -domain 3-metal cluster sites.¹⁴ This dynamic aspect of MT structure was deduced from ¹¹³Cd NMR saturation transfer studies that showed that the lifetime of a Cd²⁺ ion in a 3-metal cluster site is only about 1 s. By demonstrating that saturation transfer occurs between different MT isoforms, it was inferred that metal ions continually move from the β -domain of one MT molecule to that of another via a series of metal–ligand exchange reactions.¹⁴ The dynamics predicted by this model, involving many individual metal–thiolate bond making and bond breaking events, is what is believed to be responsible for the chemical exchange broadening of resonance III in Figure 4 as well as the temperature-dependent modulation of the widths of the other β -domain signals.¹⁴

Contrary to what one might expect from molecular size considerations alone, the solution tertiary structure of MTs could not be determined solely from standard, homonuclear, 2D ^1H NMR methods.⁹ The reason is twofold. There is considerable degeneracy in the amino acid composition and the tertiary protein fold is practically devoid of regular elements of secondary structure. The latter is reflected in the relatively small number of ^1H – ^1H NOE distance constraints that results from

In the case of ^{113}Cd MTs, additional constraints corresponding to the metal–protein coordination bonds were generated from ^1H – ^{113}Cd HMQC experiments^{15–17} that relate each ^{113}Cd resonance to the C- βH_2 protons of the coordinating Cys residues. Such information combined with the sequential ^1H NMR assignments unequivocally established the topology of the Cd–thiolate clusters and their position with respect to the MT primary structure (Figure 8). Similarly, the isomorphic replacement of the Cu(I) in yeast copper–MT by the spin- $\frac{1}{2}$ ^{109}Ag (I) ion allowed individual ^{109}Ag resonances to be correlated with their associated Cys ligands (Figure 9). These data indicated the presence of a single $\text{Ag}_7\text{Cys}_{10}$ cluster with mixed metal–coordination number.^{18,19}

The diagram illustrates the domain organization of the E-cadherin protein. The protein sequence is shown as a linear chain of amino acids: M-D-F-N-S-A-A-G-D-S-T-A-G-S-K-K-E-K-T-S. The sequence is divided into two parts by a disulfide bond (S-S). The first part contains the extracellular domains (Cd IV, Cd III, Cd II) and the second part contains the transmembrane domain (Cd I, Cd VI, Cd VII, Cd V). The domains are represented by black circles and connected by lines to their corresponding amino acid sequences.

Figure 8 Cadmium–cysteine connectivities of human MT-2 established by 2D ^1H – ^{113}Cd HMQC NMR spectroscopy. The metals are numbered according to their increasing ^{113}Cd NMR chemical shifts. The darkened residues represent cysteine

Figure 9 Heteronuclear ^1H – ^{109}Ag multiple quantum coherence transfer spectrum of yeast Ag–MT acquired *antiphase*. The seven ^{109}Ag resonances are labeled by Roman numerals according to their increasing chemical shifts. The positions of seven low-intensity ^{109}Ag resonances are indicated by the letter m. The assignments of various cross peaks along ω_2 to specific H^β of cysteine obtained from sequential assignment methods are indicated on the top of the diagram

resonances only from the X-coupled protons. Such experiments permit a straightforward measurement of ^{113}Cd – ^1H coupling constants and a direct distinction to be made between bridging and terminal Cys ligands in the MT metal clusters.²⁰

The knowledge of the metal cluster geometries and metal–Cys connectivities, together with the experimentally determined ^1H – ^1H distance constraints and the dihedral angle constraints from the measured coupling constants allowed the elucidation of the 3D solution structure of rabbit, rat, human, crab, and yeast MTs.^{21–25} In all mammalian MTs, despite some amino acid substitutions, the polypeptide wraps around the metal–thiolate clusters in a closely similar way (Figure 10) and there is conservation of local structural features. As a result of the absence of interdomain constraints, their relative orientation cannot be obtained from NMR, only from the X-ray crystal structure of rat MT, which showed identical molecular architecture with the solution structure.²⁶

1 INTRODUCTION

The information provided by the frequency dependence ('dispersion') of spin-lattice relaxation times (or rates) in the laboratory frame T_1 (T_1^{-1}), or in the rotating frame $T_{1\rho}$ ($T_{1\rho}^{-1}$), is the type and the timescale of molecular motion. Studies of this sort are mainly based on the field cycling [or NMR dispersion (NMRD)] technique^{1,2} often supplemented by rf pulse experiments in stationary magnetic fields. Molecular dynamics can be specified on this basis in great detail, although chemical shift distributions normally cannot be resolved.

The essence of the field cycling principle is to generate nonequilibrium spin populations by switching the magnetic field to a variable relaxation field, the flux density of which is normally lower than that of the polarization field. The relaxation curve of the magnetization is then probed point by point by switching to a fixed detection field, where the magnetization is read out in the form of a FID or a spin echo. A prerequisite of the technique is that relaxation during the switching intervals is minor. The maximum frequency is determined by technical restrictions, whereas the lower frequency limit is given by the local fields within the sample or by incompletely compensated external fields such as the Earth field. Operational order-of-magnitude ranges of the frequency are $10^3 < \nu < 10^8$ Hz for protons and $10^2 < \nu < 10^7$ Hz for deuterons.

Molecular motions cause fluctuations of the spin interactions; these are normally the dipolar interaction among the spin-bearing particles or the coupling of quadrupole nuclei to electric field gradients. The fluctuating interactions induce spin transitions, making the ensemble relax towards equilibrium. The spin-lattice relaxation rate $1/T_1$ in *homogeneous systems* is given by intensity functions (or spectral densities) $I(\omega)$ at the transition frequencies ω of the spin system.³ These functions are proportional to the FTs of the time autocorrelation functions of spherical harmonics of order 2, $G(t)$. The fluctuations of quadrupolar interactions and the low-frequency part of

fluctuations of dipolar interactions are normally dominated by intramolecular contributions. The T_1 frequency dispersion thus probes the correlation function (or the corresponding intensity function) of molecular reorientations and, in certain circumstances, translations.

Systems of biological origin tend to be *heterogeneous* in the sense that the investigated nuclei occur in different environments with different molecular dynamics and spin interactions. It is then a matter of exchange rates whether spin-lattice relaxation is determined by average intensity functions ('fast exchange' relative to relaxation times) so that monoexponential relaxation decays arise, or whether multiexponential distributions occur.⁴ In the context of water relaxation in biological systems, the two-site fast exchange model turned out to be very successful. Note, however, that the term 'exchange' refers to material transport as well as to (immaterial) spin diffusion or magnetization transfer.^{12,13}

The element usually detected in T_1 frequency dispersion experiments is hydrogen, via proton or deuteron resonance. (In exceptional cases, ^{31}P relaxation studies might also be feasible.⁵) Other nuclear species can be probed indirectly via cross relaxation if their relaxation rates are fast enough to act in combination with proton spin diffusion as relaxation sinks. This can be expected in particular with quadrupole nuclei. The cross relaxation then manifests itself as 'quadrupole dips' at the resonance crossing frequencies,⁶ as demonstrated in Figure 1 for polyaniline protons cross relaxed by the amide ^{14}N relaxation sinks.

The T_1 frequency dispersion may be influenced further by electron paramagnetic constituents such as, for example, molecular oxygen,⁸ paramagnetic ions,^{9,10} or heme groups.^{7,11} Relaxation mechanisms of this sort, however, are not considered in this article.

T_1 frequency dispersion studies have been performed with many different (diamagnetic) systems of biological origin, including: dissolved,^{12,14} wet,¹⁵ or dry¹⁶ proteins; DNA;⁶ lipid bilayers;^{17,18} tissue;¹⁵ eye lenses;¹⁹ and small animals *in vivo*.²⁰

The dominant constituents of biological systems are biopolymers (or oligomers) and water. The water component (including all exchangeable hydrogen atoms of the biopolymers) can be conveniently prepared in deuterated form so that separate studies of the dynamics in the two components can be performed. Figure 2 shows the T_1 frequency dispersions of water deuterons and of nonexchangeable biopolymer protons measured in a solution of bovine serum albumin (BSA) in D_2O as a typical system.²¹ The entirely different nature of the fluctuations within the two constituents is obvious.

2 FLUCTUATIONS IN PROTEINS

Molecular motions of proteins can comprise main chain ('backbone') fluctuations, side-group motions and tumbling of the whole macromolecule. The latter can easily be identified by considering the concentration dependence of the reorientation rates (see below). Side-group motions, such as restricted rotational diffusion and ring flips, are a matter of the local structure and chemical composition. Proteins, for instance, therefore tend to be characterized by a broad distribution of the side-group correlation times.

Figure 1 (a) Field dependence of the ^1H and ^{14}N resonance frequencies of amide groups. The hatched areas indicate the range covered in a powdery sample. The solid lines within these areas represent the powder averages. The magnetic flux density B_0 is expressed in units of the proton Larmor frequency. (b) T_1 frequency dispersion of poly-L-alanine at -1°C . The three ^{14}N - ^1H quadrupole dips at the resonance crossings are obvious. (Reproduced by permission of Academic Press from R. Kimmich, F. Winter, W. Nussler, and K.-H. Spohn, *J. Magn. Reson.*, 1986, **68**, 263)

Backbone fluctuations in proteins and polypeptides, on the other hand, appear to be governed by homogeneous modes leading to an apparently universal T_1 dispersion behavior at low frequencies where side-group motions are of minor importance. The frequency dependence in the absence of molecular tumbling can be described over a wide range by the power law⁶ $T_1 \propto \nu^{0.74 \pm 0.06}$, which can be explained by one-dimensional multiple trapping diffusion of defects locally dilating the structure.¹⁶ The corresponding correlation function is given by the error function ('erf') expression:

$$G_{\text{mtd}}(t) = a_1 \left\{ \text{erf} \left(\frac{b^2}{2\langle \xi^2 \rangle} \right)^{1/2} - \left(\frac{2\langle \xi^2 \rangle}{\pi b^2} \right)^{1/2} \times \left[1 - \exp \left(-\frac{b^2}{2\langle \xi^2 \rangle} \right) \right] \right\} + a_2 \quad (1)$$

Figure 2 Frequency dependence of the proton (●) and deuteron (○) spin-lattice relaxation times of a D_2O solution of bovine serum albumin (35 wt.%) at 291 K. The data in the vicinity of the ^{14}N - ^1H quadrupole dips are omitted. The different T_1 frequency dispersions indicate different fluctuation processes dominant for water (including exchangeable hydrogen atoms) and for the protein molecules. (Reproduced by permission of the American Chemical Society from W. Nussler and R. Kimmich, *J. Phys. Chem.*, 1990, **94**, 5637)

where $a_2 = 1 - a_1$ represents the residual correlation at long times, b represents the extension of the defect, and $\langle \xi^2 \rangle \propto t^{1/2}$ represents the (anomalous) mean-square displacement of the defects in a time interval t .

3 FLUCTUATIONS IN LIPID BILAYERS

Lipid bilayers form another system whose dynamics are governed by dynamic modes. In experiments with partially deuterated samples, one can distinguish between the alkyl chain and the headgroup part of the bilayers. In the gel phase, one-dimensional restricted diffusion of defects (chain orientation conserving rotational isomers) permits the perfect description of the T_1 frequency dispersion of the alkyl chains.¹⁷ The corresponding intensity function for defect diffusion is characterized by the limits

$$I_{\text{dd}}(\omega) = \begin{cases} \frac{2}{3}(\tau_b^{1/2}\tau_d^{1/2} - \tau_b) & \text{for } \omega\tau_d \ll 1 \\ \frac{\tau_d\tau_b^{1/2} - 2\tau_b\tau_d^{1/2}}{(\tau_d^{1/2} - \tau_b^{1/2})^2} \omega^{-1/2} & \text{for } \omega\tau_b \ll 1 \ll \omega\tau_d \\ \frac{\tau_d^{1/2}}{\tau_d^{1/2} - \tau_b^{1/2}} \omega^{-3/2} & \text{for } \omega\tau_b \gg 1 \end{cases} \quad (2)$$

where τ_d is the mean diffusion time across the bilayer (from headgroup to headgroup) and τ_b is the mean diffusion time over a length equal to the width of the defect.

In the liquid crystalline phase, collective modes ('director fluctuations') tend to dominate at low frequencies.¹⁸ The behavior is, however, much more complex because other mechanisms such as rotational isomerism, chain rotations, and diffusion along the curved shape of the bilayer are superimposed.

4 DEUTERON T_1 FREQUENCY DISPERSION OF PROTEIN SOLUTIONS IN D_2O

The proton signals observed in tissue, diluted aqueous biopolymer solutions, and diluted aqueous lipid bilayer dispersions tend to be dominated by water. In such systems, the polar surfaces of the macromolecular constituents are covered by hydration shells; however, these shells form only a minor fraction of the total water. Nevertheless, a strong enhancement of the spin–lattice relaxation of water occurs as first observed in protein solutions.²²

Also at a rather early stage, it was found by means of NMR spectroscopy that water molecules in the hydration shell are oriented relative to the biopolymer surface^{23,24} and congeal far below the freezing point of bulk water.²⁵ Nonfreezing water actually may be an operational definition of hydration water, the fraction of which can be quantitatively determined in this way.

Another striking finding is that translational diffusion within the hydration shells is relatively fast. Even in frozen protein solutions not far below 0°C, where diffusion is restricted to thin (about a monolayer thick) films of liquid water on the surface of the macromolecules, the diffusion coefficient is merely reduced by one order of magnitude relative to liquid bulk water.²⁶ On the other hand, orientation correlation times up to six orders of magnitude longer than those in bulk water must be concluded from T_1 frequency dispersion experiments.¹⁵

The T_1 frequency dispersion of the water phases in protein/ D_2O solutions was measured selectively using deuterium resonance.¹⁵ In the frame of the two-site fast exchange model, the effective water spin–lattice relaxation rate is given by:

$$\frac{1}{T_1} \approx \frac{1 - p_h}{T_1^f} + \frac{p_h}{T_1^h} \quad (3)$$

where T_1^f and T_1^h are the spin–lattice relaxation times in the ‘free’ (i.e. bulk) and ‘hydration’ water phases, respectively, and p_h is the fraction of hydration water.

The description of the T_1 frequency dispersion of hydration water is principally based on four competitive mechanisms:

1. Tumbling of the macromolecule including its hydration shell (correlation time τ_t).
2. Restricted rotational diffusion of water molecules about axes perpendicular to the local surface (correlation time τ_r).
3. Exchange between free and hydration water (correlation time = residence time in the hydration shell $\tau_\perp$).
4. Reorientations mediated by translational displacements (RMTDs) along the more or less rugged and curved surface of the macromolecule: water molecules diffuse along the surface and, as a consequence, alter their orientations which are defined by the local surface structure. The longest correlation of this mechanism is designated by $\tau_\parallel$.

Using the orientational structure factor formalism,²⁷ the RMTD correlation function was derived as:

$$G_{\text{RMTD}}(t) = \frac{1}{2(k_u - k_l)} \sqrt{\frac{\pi}{Dt}} [\text{erf}(\sqrt{Dt}k_u) - \text{erf}(\sqrt{Dt}k_l)] \quad (4)$$

where k_u and k_l are the upper and lower cut-off wavenumbers of the equipartition distribution assumed for the surface

Figure 3 Deuteron T_1 frequency dispersion of D_2O solutions of bovine serum albumin at 291 K. The solid lines were calculated using the RMTD formalism taking into account protein tumbling [equation (8)] and restricted rotational diffusion of the water molecules (high-frequency regime). Note that the T_1 frequency dispersions at a water content of 25 wt.% (no free water) and 50 wt.% (with free water) are qualitatively the same, apart from differences in the absolute values of the relaxation times. In these cases, the low-frequency dispersion is dominated by RMTD. At 75 wt.%, the inflection point is shifted to higher frequencies due to the competitive action of protein tumbling. (Reproduced by permission of Elsevier from R. Kimmich, W. Nusser, and T. Gneiting, *Colloids Surf.*, 1990, **45**, 283)

structure. D is the average translational water diffusion coefficient in the hydration shell. The lower cut-off wavenumber is connected with a cut-off correlation time:

$$\tau_\parallel = (Dk_l^2)^{-1} \quad (5)$$

revealing itself as the ‘inflection point’ $2\pi\nu\tau_\parallel \approx 1$ in the absence of molecular tumbling (see Figure 3). Equation (4) produces the square root frequency dependence typical for water relaxation in aqueous protein solutions at intermediate frequencies.

Restricted rotational diffusion, exchange with free water and macromolecular tumbling can be represented by exponential correlation function. Restricted rotational diffusion is only important for the high-frequency dispersion, whereas the exchange mechanism is normally too slow (relative to the other contributions) to affect the reorientation behavior. What remains as a mechanism effective in the low-frequency regime is macromolecular tumbling and RMTD.

On the basis of this scheme, the deuteron T_1 frequency dispersion of D_2O in aqueous protein solutions can be described perfectly.¹⁵ Inserting the water diffusion coefficient experimentally determined with the NMR field gradient technique, a length scale can be estimated from the RMTD correlation time $\tau_\parallel$ [equation (5)] revealing itself via the inflection point in the absence of macromolecular tumbling. The result is half the protein circumference, as required by RMTD.²⁷ In other words, the mean diffusion time around half the circumference of the protein molecule is calculated, on the basis of the experimental diffusion coefficient and the known short and long axes of the protein, to be of the order of 10^{-6} s, which is in perfect agreement with the inflection point measured in the absence of macromolecular tumbling.

The RMTD mechanism accounts very well for the weak temperature dependence of spin–lattice relaxation. Transient irrotational binding of a small percentage of the hydration water at certain sites, as suggested in several studies,^{22,28} would require binding energies twice as high as the apparent activation energies estimated from the experimental T_1 data. With RMTD, long correlation times are due to the geometry of the system rather than to high binding energies at certain sites. Furthermore, transient irrotational binding would result in slopes of the T_1 frequency dispersion at intermediate frequencies which are four times as high as found experimentally.

Another question is the origin of the long residence times of water molecules in the hydration shells. This, of course, is no problem, in principle, if free water is absent or frozen. Adding more and more water to a protein sample which initially has saturated hydration shells but no free water, does not change the qualitative behavior of relaxation or diffusion.^{15,26} With the exception of the onset of macromolecular tumbling (described below), there is no evidence for new relaxation mechanisms of hydration water due to the presence of free water.

The relaxation scheme outlined above can also be applied to a certain degree to systems modeling hydrated globular proteins. Water adsorbed on agglomerates of fine particles of silica of a similar diameter again shows a T_1 frequency dispersion reflecting the surface structure.³⁰

While the surfaces of fine particles of silica are expected to be smooth and chemically homogeneous, those of proteins are extremely heterogeneous with respect to polarity and hydrogen binding ability. On such surfaces water diffusion is more likely to resemble a hopping process among the preferential binding sites or areas. Translational displacements may then be governed by waiting time and step-length distributions.³¹ Nevertheless, in timescales that are long compared with typical waiting times, i.e. in the fast-jump limit, an effective diffusion coefficient can be defined. This also includes exchange processes in the sense that molecules (or hydrogen atoms) leave and reenter the hydration shell to and from other environments such as free water or sites within the protein. In this case, the surface is probed only selectively by a set of discrete binding sites. Correspondingly, the spin–lattice relaxation then originates from reorientation jumps.

From the experimental point of view, the fast jump/exchange limit reveals itself by giving monoexponential attenuation curves in diffusion as well as in spin–lattice relaxation experiments. This is what one normally observes, to a reasonably good approximation.²⁶ In this case, effective diffusion coefficients D_{eff} and effective spin–lattice relaxation times $T_{1,\text{eff}}$ can be evaluated.

The microphases (or molecular environments) can be characterized by weights p_i , diffusion coefficients D_i , and spin–lattice relaxation times $T_{1,i}$. The following exchange formulas are then valid:

$$D_{\text{eff}} = \sum_i p_i D_i \quad (6)$$

$$\frac{1}{T_{1,\text{eff}}} = \sum_i \frac{p_i}{T_{1,i}} \quad (7)$$

where $\sum_i p_i = 1$.

D_{eff} tends to be governed by environments with high molecular mobility, whereas $1/T_{1,\text{eff}}$ is dominated by the slowly reorienting molecules, that sit for relatively long periods on sites with certain orientations. Thus, high effective diffusion coefficients, long orientation correlation times, and low thermal activation energies do not contradict each other a priori.

If distributions of microphases exist, the continuous-diffusion treatment must be regarded as an approximate description of phenomena that tend to be discrete in reality. RMTD in this case probes only those sites of the surface at which spin–lattice relaxation effectively takes place (irrespective of the exchange pathways that the molecules or atoms follow in between). In principle, the applicability of the concept comprises continuous and step-by-step, surface-bound and multiphase diffusion, as long as the experiments provide *effective* diffusion coefficients and spin–lattice relaxation times.

5 CRITICAL WATER CONTENTS

In the limit of low frequencies, the T_1 frequency dispersion of water in protein solutions terminates at a certain ‘inflection frequency’ ν_i in a plateau (see Figure 2 and Figure 3). As an indication of the competitive nature of RMTD and macromolecular tumbling, this quantity depends strongly on the water content c_w (Figure 4).²⁹

Tumbling can only take place if the water content exceeds the saturation concentration c_s defined by the saturation of

Figure 4 Inflection frequency of the deuteron T_1 dispersion of BSA/D₂O solutions at 291 K versus water content. This dependence can be described by the ‘free-water volume’ model of macromolecular tumbling illustrated in the upper left-hand corner of the diagram. A protein molecule (P) including hydration water (HW) can only tumble if sufficient free water (FW) is available. The minimum free-water volume corresponds to the circumscribing sphere. Below a critical water content $c_0 \approx 65$ wt.%, macromolecular tumbling is slower than the RMTD process of water on the surface, so that the inflection frequency is governed by RMTD. Above c_0 , tumbling becomes faster than this limit. The inflection frequency is then determined by the tumbling rate of the macromolecules. The experimental data were evaluated directly from the T_1 dispersion curves, the solid line was calculated on the basis of the formalism described in the text. (Reproduced by permission of Hühig & Wepf from R. Kimmich, *Makromol. Chem., Macromol. Symp.*, 1990, **34**, 237)

the hydration shells. In this case ‘free water’ is present so that, with a certain probability, a macromolecule is surrounded by enough free water for rotational jumps. The ‘free-water volume’ formalism¹⁵ leads to a macromolecular tumbling correlation time:

$$\tau_t = \tau_t^0 \exp \left[\gamma^* (r - 1) \frac{1 - c_w + c_s}{c_w - c_s} \right] (c_w) c_s \quad (8)$$

where $\tau_t^0 = \eta(v_p + v_s)/(k_B T)$ is the Stokes–Einstein expression for tumbling of a particle with volume $v_p + v_s$ (bare protein plus the saturated hydration shell) in a solvent with viscosity η ; $0.5 < \gamma^* < 1$ is a numerical constant; and r is the ratio of the volumes of the circumscribing sphere and the hydrated protein molecule itself approximated by an ellipsoid (see Figure 4). The critical water content c_0 at which macromolecular tumbling becomes competitive to the correlation time $\tau_{\parallel}$ corresponding to the lower cut-off wavenumber k_1 of the RMTD process, is then defined by the condition $\tau_{\parallel} = \tau_t$. From this, one finds that

$$c_0 = c_s + \frac{\tilde{\gamma}}{1 + \tilde{\gamma}} \quad (9)$$

where $\tilde{\gamma} = (r - 1)\gamma^* / \ln(\tau_{\parallel}/\tau_t^0)$. For aqueous bovine serum albumin (BSA) solutions, $c_s \approx 30$ wt.% and $c_0 \approx 65$ wt.%, that is $\tilde{\gamma} \approx 0.5$.

6 PROTON T_1 FREQUENCY DISPERSION OF TISSUE

Although water is normally the most abundant compound in tissue, and therefore provides the dominant contribution to hydrogen signals recorded in relaxation experiments, the

Figure 5 Proton T_1 frequency dispersion of a leech (in vivo) and freshly excised frog sartorius muscle (FSM) in the relaxed state in vitro. The solid lines were calculated on the basis of macromolecular tumbling, RMTD, restricted rotational diffusion of hydration water, protein backbone fluctuations and terms representing the ^{14}N – ^1H cross relaxation quadrupole dipoles. (Reproduced by permission of Elsevier from R. Kimmich, W. Nussler, and T. Gneiting, *Colloid. Surf.*, 1990, **45**, 283)

behavior observed in tissue is determined by the interaction and the cross relaxation with the macromolecular constituents. The description must therefore refer to fluctuations in the water phases as well as in the macromolecules. Assuming fast exchange between all components, it is possible to reproduce the experimental T_1 frequency dispersion of tissue by considering the combined action of RMTD in the hydration shells, tumbling and backbone fluctuations of the proteins, restricted rotational diffusion of hydration water molecules, and (with regard to the quadrupole dip frequency region) ^{14}N – ^1H cross relaxation. Figure 5 shows two representative data sets.¹⁵

Treatments of this sort are crucial for our understanding of the basic mechanisms contributing to relaxation in tissue. For the practical characterization of tissue, it may be more useful to describe the T_1 frequency dispersion by empirical intensity functions or just qualitatively. The T_1 frequency dispersion of a number of different tissues have been characterized in this way, showing significant differences.^{32–34}

7 $T_{1\rho}$ FREQUENCY DISPERSION IMAGING

The molecular motions revealing themselves in the T_1 frequency dispersion are substantial for image contrasts in

Figure 6 Cross-sectional NMR images of a mouse with an implanted tumor (left). (a) Conventional two-dimensional spin echo FT image. (b) Rotating frame dispersion image (RODI) rendering the $T_{1\rho}$ frequency dispersion as gray scale contrasts. The tumorous tissue (left) can be clearly distinguished from muscle tissue (right). NMR tomography. At conventional magnetic flux densities, the relaxation contrasts originate from relative fast motions and represent the relaxation rates rather than the T_1 frequency dispersion. Using on- and off-resonance variants of spin–lattice relaxation in the rotating frame, an imaging sequence was proposed that gives directly the spatial distribution of the $T_{1\rho}$ frequency dispersion,^{35,36} which is indicative for slow motions, macromolecular tumbling, and RMTD.

Figure 6 shows images of a tumorous mouse recorded with this rotating frame dispersion imaging (RODI) technique and conventional tomography for comparison. Striking differences are obvious. RODI provides strong contrast of the tumorous tissue, whereas muscle tissue is suppressed. In the conventional spin echo FT image, on the other hand, both sorts of tissue are rendered with equivalent intensity. Thus biomedical applications of the low-frequency dispersion of spin–lattice relaxation suggest themselves.

1 INTRODUCTION

Muscle tissue is important in the body for producing motion, pumping the heart, and operating the viscera and blood vessels. These muscles can be classified into three categories: skeletal, cardiac, and smooth. Skeletal and cardiac muscles are very similar in protein content, but differ in their mechanism of excitation–contraction coupling.¹ Smooth muscles, on the other hand, are different, and because they are more difficult to work with experimentally, are not as well understood. The events leading to muscle contraction involve a complex set of proteins, all acting together. In this article we concentrate on the most well studied skeletal and cardiac muscle proteins.

Skeletal and cardiac muscles are composed of a large number of multinucleated cells. Muscle cells are composed of fibers surrounded by an electrically excitable membrane called the sarcolemma. The fibers consist of myofibrils which are bundles of several hundred protein filaments in parallel.² Of particular importance is the presence of a network of tubules surrounding the myofibrils called the sarcoplasmic reticulum (SR). The SR is an intracellular store of calcium ions and contains proteins which are involved in the release and uptake of calcium. The myofibrils consist of what are called thick and thin filaments due to the way that they look under a microscope.² The thick filament is composed of myosin and its associated light chains, whereas the thin filament is composed of actin, tropomyosin, and the troponin complex (troponin I (TnI), troponin T (TnT), and troponin C (TnC)).

Muscle contraction in skeletal muscle starts by the transmission of an impulse through a motor nerve. This gives rise to action potentials which are conducted down the transverse tubules.¹ Depolarization of the transverse tubule membrane results in release of calcium into the sarcoplasm. In the resting state of muscle, the interaction of actin with myosin is inhibited by tropomyosin and the troponin complex. When calcium is released by the SR, TnC binds calcium which then confers a conformational change throughout the troponin complex and tropomyosin and releases the inhibition of the interaction of actin with myosin. The myosin ATPase then hydrolyzes adenosine as in adenosine triphosphate (ATP), resulting in shortening of the muscle (sliding of the filaments past one another), or contraction.

For muscle contraction to occur, there must be a very tight association and communication between the proteins. For this

reason and the fact that the proteins actually involved in the muscle contraction are very large, NMR of muscle proteins is a difficult task. Novel techniques have been developed in order to study these proteins, and most of these techniques are discussed in this article. The discussion in this article is restricted to the proteins of the thick and thin filaments and a few of the other proteins of the muscle system. Ion binding using ¹¹³Cd NMR, ⁴³Ca NMR, and ²³Na NMR are not discussed here, as this is covered elsewhere in the Encyclopedia.

One final protein of note is parvalbumin. Parvalbumin is a protein present in the sarcoplasm and has been described as a calcium carrier between the myofibril and the SR, behaving as a soluble relaxing factor.³ Being soluble, smaller than, and homologous to the calcium binding protein TnC, it has been studied quite extensively by NMR.

2 THICK FILAMENT PROTEINS

Myosin is the major protein in the thick filament [Figure 1(a)]. The complex (MW 520 kDa) consists of two (220 kDa) heavy chains and four light chains that are between 15 and 22 kDa in size.⁴ Each heavy chain forms a globular head, which contains an actin binding site and a nucleotide binding (ATPase active) site. Each chain also contains a long C-terminal α -helical tail which combines with another heavy chain to form the coiled-coil thick filament backbone. Myosin can be cleaved proteolytically by trypsin⁵ into light meromyosin (the C-terminal coiled-coil portion of myosin) and heavy meromyosin (the N-terminal portion of myosin containing the two globular heads and a portion of the coiled-coil structure). Further digestion of heavy meromyosin (HMM) by papain results in two globular heads with their associated light chains (S1) and the coiled-coil hinge region (S2)⁵ [Figure 1(b)].

The crystal structure of myosin S1 has been determined to 0.28 nm resolution⁴ and is found to be 45% α -helical. The nucleotide binding pocket is formed from several different α -helical and loop regions of the molecule. Of particular interest is an α -helical region which lies under the binding site. This contains the two highly reactive sulfhydryl groups SH₁ and SH₂ (cysteine-707 and cysteine-697), which have been labeled and studied in many chemical and spectroscopic studies. These cysteines lie in small clefts that face toward the solvent on opposite sides of the molecule. The actin binding site appears to be on the opposite side of the S1 head to the nucleotide binding site.⁴ Associated with the globular S1 head are the essential and regulatory light chains. The essential light chain interacts with the C-terminal long helical end of S1, which presumably joins up to the α -helical coiled-coil backbone [Figure 1(a)]. This light chain appears to have conformational flexibility in the crystal structure.⁴ The regulatory light chain interacts with the region further to the C-terminal end of S1.⁴ Both the essential and regulatory light chains share sequence similarity and structural homology to calmodulin and TnC, although only one divalent cation binding site is still functional.

There have been many NMR studies of intact myosin,^{6–11} the light chains,^{12–20} the nucleotide binding site,^{21–32} the actin binding site,^{7,13,18,19,33,34} the S2 region,³⁵ and light meromyosin (LMM).³⁶

Figure 1 (a) Schematic diagram of the myosin molecule. Shown in green are the two heavy chains which form globular heads at their N-terminus (containing the actin binding site and the nucleotide binding site), and wind around one another at their C-terminus to form an α -helical coiled coil. Shown in red and yellow are the essential and regulatory light chains, respectively. (b) Cleavage products of myosin. Myosin may be enzymatically cleaved with trypsin to form two cleavage products: LMM (light meromyosin) and HMM (heavy meromyosin) containing the globular heads, their associated light chains and a portion of the coiled-coil tail of myosin. HMM may be further cleaved by papain into S2 (coiled-coil hinge region) and S1 (myosin globular heads with its associated light chains)

2.1 Myosin

One of the first NMR studies on skeletal myosin used 360 MHz ^1H NMR to compare spectra of myosin, HMM, S1, and LMM.⁷ The results were quite striking in that myosin, HMM, and S1 all exhibited sharp resonance lines due to a high mobility of some amino acids. Careful ^1H NMR spin echo studies on gizzard myosin also illustrated mobility arising predominantly from the myosin S1 units.¹⁰ This increased mobility was also observed in ^1H spectra of skinned muscle fibers¹¹ and ^{13}C NMR spectra of S1.⁹ ATP binding,⁷ surface-directed paramagnetic probes,⁸ or solvent viscosity⁸ had no effect on these sharp, mobile resonances. One proposal was

that the mobility arose from a disordered interior;^{7,8} however, it was shown that this mobility arose from at least one of the light chains.^{13,17} Indeed, the crystal structure⁴ supports the latter hypothesis.

2.1.1 Nucleotide Binding Site

There have been two types of study to monitor the mobility of the bound nucleotide in the ATPase site. One of these studies monitored mobility of the γ -phosphate of ATP,²¹ while the other study monitored the mobility of the adenine ring.²⁷ To monitor the γ -phosphate mobility, ^{31}P NMR was employed to study the time-course of ^{18}O exchange between $[\text{O}^{18}]\text{Pi}$ and H_2O catalyzed by S1 in the presence of MgADP .²¹ All the $[\text{O}^{18}]\text{Pi}$ that bound to S1 underwent complete exchange and was released as $[\text{O}^{16}]\text{Pi}$, indicating that this phosphate interconverted rapidly between $\text{M}^{**}\text{ADP} \cdot \text{Pi}$ and $\text{M}^* \cdot \text{ATP} + \text{H}_2\text{O}$. Using 2-fluoro-ADP bound to S1,²⁷ a rotational correlation time close to myosin S1 itself was observed for the ^{19}F resonance, indicating a relatively constrained adenine ring.

Recently, two new reagents have been found to trap ADP in the nucleotide binding site of S1 and to inhibit the ATPase activity of S1. These reagents are aluminum fluoride and beryllium fluoride.^{31,32} These tetrahedral fluoroaluminate and fluoroberyllate anions act as phosphate analogs binding to the position normally occupied by the γ -phosphate of ATP. Neither the myosin-ADP-fluoroaluminate nor the myosin-ADP-fluoroberyllate complex could bind to actin.³² When fluoroberyllate bound to S1, it bound as one of four complexes, depending on how much it was hydroxylated.

The response of S1 or HMM to nucleotide binding was monitored by labeling S1²⁶ or HMM²⁸ with *N*-(4-trifluoromethylphenyl)iodoacetamide. The SH_1 group was preferentially modified in each case. S1 was found to exist in two discrete states under a wide variety of conditions.²⁶ Furthermore, these states could exist in the absence of nucleotide, and one of the states was identical with the state induced by binding $\text{Mg} \cdot \text{ADP}$ or magnesium:adenosine $5'\text{-}\beta,\gamma$ -imidotriphosphate to the active site.²⁶ HMM was found to behave almost identically to S1, except for a hysteresis-like effect in which the ^{19}F NMR chemical shift depended on the temperature at which the previous experiment had been performed.²⁸ These data indicated a coupling of the globular region with a second region forming a distinctly different cooperative unit than the one present in the S1 monomer alone.²⁸

2.1.2 Actin Binding Site

The study of myosin binding to actin has revealed two binding sites on myosin. The first site belongs to the essential light chain's [S1(A1)] N-terminal 41-residue segment,^{18,19,33} and the second site is close to the SH_1 group on S1.³⁷

As actin was titrated into S1, the narrow ^1H NMR resonances (see above) in the aliphatic region reduced and disappeared as the actin/myosin ratio was increased to more than 1:1.^{7,13,18,19,33} Nucleotide binding to this complex restored the sharp, mobile resonance lines by dissociation of the acto-S1 complex. It was found that there was an interaction between the N-terminal 41-residue segment of S1(A1) and, in particular, the *N*-trimethyl group of S1(A1) (see below) and actin.^{18,19,33} Covalently labeling cysteine-374 of actin (near the C-terminus) with a spin label and

monitoring the signal arising from the *N*-trimethyl protons revealed a broadening upon actin binding, indicating that these protons are close (within 1.5 nm) to the C-terminus of actin.¹⁹ The N-terminal region of S1(A1) was also found to alter the thermodynamic characteristics of the regulated acto–S1 interaction, thus operating as a functional linkage in the thin filament based regulatory mechanism.¹⁸ LC2 (see below) did not display binding to actin.¹⁸

The two accessible cysteine groups of S1 (SH₁ and SH₂), modified by (trifluoromethyl)mercuric bromide, illustrated significant broadening in the ¹⁹F spectrum of SH₁, while broadening of SH₂ occurred to a lesser extent upon binding of actin.³⁸ The binding site of S1 for actin was therefore inferred to be closer to SH₁ than SH₂.

2.1.3 S2

S2 is the portion of HMM that connects S1 to LMM. It has been thought that this region of myosin contains a hinge, which aids in the power stroke of myosin. Stewart and Roberts³⁵ have used NMR to see if a flexible region associated with a hinge could be identified. They were able to observe some sharp resonances (probably due to side-chain mobility), but not enough to suggest a major flexible region.

2.1.4 LMM

Kalbitzer et al.³⁶ studied the C-terminal portion of LMM (262 amino acids) by ¹H NMR and determined that these molecules assemble to form an α -helical coiled-coil structure as is found in myosin. The last 12 C-terminal residues of one polypeptide chain and the last nine C-terminal residues of the other chain are very mobile. This unfolded character probably aids in the assembly into thick filaments.

2.2 Essential Light Chain

The essential or alkali light chain has two isoforms referred to as A1 (MW 25 kDa) and A2 (MW 17 kDa). These isoforms have an identical 141 residue C-terminus and are homologous over the preceding eight residues. A1 differs from A2 in that it possesses a 41 residue N-terminal tail rich in proline, alanine, and lysine residues. Difference ¹H NMR spectra of S1(A1) and S1(A2) reveal resonances arising from lysine, alanine, and proline,^{13,17} which arise from the additional 41 amino acids found at the N-terminus of A1. In particular, there is an intense resonance in the spectrum at 3.23 ppm attributed to an N-terminal *N*-trimethyl blocking group.¹⁴ Isolation of residues 1 to 37 of A1 revealed that the proline residues were primarily in the *trans* configuration, consistent with an elongated structure.¹⁸ Furthermore, this conformation was found to be present in intact S1, suggesting that this segment may undergo lateral and rotational diffusion independent of the rest of the complex. The *N*-trimethyl group of the essential light chain was found to be less than 1.5 nm away from an SH₁ spin label on the heavy chain.¹⁹

2.3 Regulatory Light Chain

The regulatory 5,5'-dithiobis-2-nitrobenzoic acid light chain LC2 is thought to play a role in modulating the actomyosin

interaction during long-term stimulation of muscle.¹⁶ LC2 may be phosphorylated at serine-14 or -15. ³¹P NMR of phosphorylated LC2 attached to whole myosin revealed a linewidth of 40 Hz, indicating significant internal mobility of the phosphate of LC2. When the light chains were purified, a linewidth of 10 Hz was obtained.^{12,20} This light chain also contains *N*-trimethyl protons, but the lines of these are broader than for LC1, indicating less mobility.¹⁵ The segmental mobility of the N-terminal region of the LC2 light chain is independent of the rest of the molecule due to the relatively narrow linewidths when attached to whole myosin. ¹⁹F NMR on S1, labeled with *N*-4-(trifluoromethyl)phenyliodoacetamide or *N*-3,5-di(trifluoromethyl)phenyliodoacetamide at SH₁, complexed with LC2 has revealed that LC2 does not interact anywhere near SH₁ nor does it alter the energetics of the structural transition.¹⁶ It was also shown that papain-digested S1 in the presence of LC2 was able to bind a near stoichiometric amount of calcium with high affinity (LC2 was able to bind calcium).¹⁶

3 THIN FILAMENT PROTEINS

3.1 Actin

Actin is the major structural component of the thin filament of muscle.⁶ Actin interacts with tropomyosin and troponin in a calcium mediated manner to control muscle contraction. The interaction of actin with myosin mediates the force development in muscle (Figure 2).

In the absence of salt, actin exists as a globular protein known as G-actin. It changes upon the addition of salt into a highly asymmetrical fibrous polymer known as F-actin. Each actin monomer has 375 residues, five of which are sulfhydryl residues (residues 10, 217, 257, 285, and 374). The crystal structure of G-actin complexed with DNase I has recently been determined to 0.28 nm resolution with ATP bound and

Figure 2 Schematic diagram of the thin filament. The actin filament is composed of two strands of polymerized actin monomers. Tropomyosin, polymerized in a head-to-tail manner, lies in the grooves of the actin filament, one tropomyosin monomer spanning seven actin monomers. The troponin complex interacts with both actin and tropomyosin, the troponin T (TnT) component overlapping tropomyosin in its C-terminal region including the head-to-tail overlap. Troponin I (TnI) binds to TnC and actin and is the inhibitory component, and troponin C (TnC) is the calcium binding component responsible for the calcium sensitivity of the complex. (Reproduced by permission of The American Society for Biochemistry & Molecular Biology from D. H. Heeley, D. Golosinska, and L. B. Smillie, *J. Biol. Chem.*, 1987, **262**, 9971)

0.3 nm resolution with ADP bound.³⁹ The actin structure has two domains, with the nucleotide and calcium ion bound in the cleft between the two domains.

One of the first published ¹H NMR spectra of actin used 50 μ M actin in D₂O at a field strength of 400 MHz.⁴⁰ The spectra indicated that a number of residues in G-actin were rotationally constrained. The study of actin at low concentrations in the presence and absence of KCl, as well as a chemically modified form at higher concentrations, illustrated no observable difference of actin before it polymerized.⁴¹

Three of the easily accessible cysteine residues of G-actin (cysteine-10, -284, and -374) were modified with 3-bromo-1,1,1-trifluoropropanone^{38,42} or 4-perfluoro-*t*-butylphenyliodoacetamide,⁴³ or (trifluoromethyl)mercuric bromide.³⁸ Only cysteine-374 broadened upon polymerization, indicating that this cysteine is near the site of polymerization.^{38,42,43} The structure of ATP bound to G-actin was unaltered upon cysteine labeling as ³¹P NMR studies of the three phosphates of ATP detected no appreciable changes to the structure of actin after reaction.⁴² Furthermore, the protein could polymerize easily, indicating that the cysteine residues were not essential for polymerization.⁴²

3.1.1 Nucleotide and Ion Binding

The ³¹P NMR spectra of ATP-bound G-actin revealed a slow exchange of ATP on the NMR timescale.⁴⁴ Nitration of G-actin with tetranitromethane to form an unpolymerizable derivative did not affect ATP binding.⁴⁵ The rotational correlation times for the γ , α , and β phosphates of bound ATP were determined to be 41, 40, and 44 ns, respectively. Since the theoretical tumbling time for G-actin was determined to be 36 ns, the correlation times of the phosphates indicate that the ATP molecule is tightly bound to G-actin and that there is no appreciable rapid internal mobility.^{45,46} An electrophilic group was found to interact with the nonbridging oxygen atoms of the phosphate groups in ATP, increasing the electronegativity of those oxygen atoms.⁴⁵

³¹P NMR was used to determine that the high-affinity metal binding site and the ATP binding site are close together (less than 1.0 nm).⁴⁷ By binding Mn²⁺ to the Ca²⁺ binding site, the NMR resonances of the bound ATP in the complex were too broad to be detected due to the paramagnetic behavior of Mn²⁺. The crystal structure³⁹ confirms that the binding of calcium to G-actin involves the phosphate groups of ATP.

Actin can bind either calcium or magnesium in the muscle cell. The conformation of actin changed when calcium was substituted for magnesium in the high affinity cation binding site.⁴⁸ Mg²⁺/Ca²⁺ exchange in the primary cation site resulted in a six-fold increase in the ATP off rate, indicating that the conformational change, when magnesium binds, can be related to ATP hydrolysis.⁴²

3.1.2 Interaction of Actin with Myosin and other Proteins of the Thin Filament

There have been several studies on the interaction between actin and myosin. Upon alkylation of cysteine-10 with 3-bromo-1,1,1-trifluoropropanone, it was shown that the ¹⁹F NMR spectrum was broadened when actin was incubated with myosin S1.³⁸ Labeling of lysine-61 of actin with pentafluorophenylisothiocyanate (PFPTIC), revealed no change in the

¹⁹F spectrum when actin was polymerized, but when PFPTIC was replaced by a fluorescein-5-isothiocyanate (FITC) label, actin polymerization was prevented, probably due to the fact that FITC is much larger than PFPTIC.³⁷ Since lysine-61 was not buried when actin was polymerized, and since lysine-61 could still be modified by PFPTIC when actin was polymerized, lysine-61 must be close to the site of polymerization of actin monomers.³⁷ Binding of tropomyosin to actin broadened the linewidth of the label attached to lysine-61 beyond detection.³⁷ Addition of troponin to this mixture did not alter the broadening of the lysine-61 line.³⁷ The binding of S1 to actin resulted in a complete broadening of the lysine-61 line.³⁷ It was concluded, then, that lysine-61 is near all three binding sites (S1 binding site, tropomyosin binding site and the site of interaction between actin monomers), but furthest away from the site of actin monomer interaction. These results support the view that myosin and tropomyosin compete for the same site on actin,³⁷ and that tropomyosin and myosin bind to F-actin in the groove formed by packing of the actin monomers in the long pitch of the helices.

Another way to study the interaction of proteins is to use synthetic peptides which encompass a binding site. Two such studies have been done using NMR on actin 1–28.^{49,50} It was shown that actin 1–28 binds to S1 and increases the ATPase activity by 150%.⁴⁹ The maximal activity occurred at a peptide/HMM ratio of 0.5:1, suggesting that one peptide binds to one head of the myosin dimer, and therefore there must be cooperative interactions occurring between the two heads. Actin 1–28 binds troponin in the absence of calcium but not in the presence of calcium, indicating that the interaction between actin and TnI is sensitive to the calcium dependent changes in TnC.⁴⁹ It was also shown that TnI 104–115 successfully competes with TnI for actin 1–28. Using the transferred NOE experiment, the authors were able to determine that there is a change from an extended structure to a helix-like conformation between residues 1 and 7 of actin 1–28 when troponin is bound.⁴⁹

3.2 Tropomyosin

Tropomyosin is of central importance in the regulation of contraction. Tropomyosin serves to propagate conformational changes which start in the troponin complex with the actomyosin ATPase. Tropomyosin is composed of two polypeptide chains, each 284 amino acids long. There are two species in skeletal and cardiac muscle, α and β . Tropomyosin is in an α -helical coiled-coil conformation except for the ends, the chains being parallel and in register (Figure 2). The ends of tropomyosin overlap with one another by 8 to 11 residues in a head-to-tail fashion. Tropomyosin lies along the grooves of the double helix of F-actin with one molecule spanning seven actin monomers. There are two sets of seven zones that bind to actin. One tropomyosin molecule interacts with one troponin molecule. There have been several studies done involving tropomyosin using NMR, mainly to describe the dynamics of tropomyosin.

Early ¹H NMR work on tropomyosin, which involved observing tyrosine resonances,⁵¹ revealed that the coiled-coil structure of tropomyosin near neutral pH is a flexible, open structure in the monomeric and polymerized forms. A histidine titration^{52,53} revealed that histidine-153 has multiple

resonances, suggesting the existence of intermediates in the thermal unfolding of the tropomyosin coiled-coil and that the C-terminus is less stable than the rest of the molecule. The splitting of histidine derives from conformational differences in the local structure about the histidine residues which produce the different pK_a values.⁵³ In addition, it was shown that the two histidine residues (153 and 273), which are quite far apart on the coiled-coil (separated by 18 nm), have significant cooperativity in their pH titrations only in polymerized tropomyosin.⁵⁴ This cooperativity must derive from a common conformational transition. These data were confirmed using amide hydrogen exchange rates on smooth and cardiac tropomyosins.⁵⁵

One phosphorylation site of tropomyosin exists at the penultimate serine-283 residue, but only a small fraction of tropomyosin molecules are phosphorylated.⁵⁶ It was found that this phosphorylated serine could form salt linkages with lysines-6 and -12 to stabilize the head-to-tail overlap. It was shown that this residue is exposed to the solvent and can undergo protonation or deprotonation in the polymerized and unpolymerized state. Furthermore, the linewidth of the phosphorylated residue would suggest considerable flexibility in the monomer and polymer.⁵⁶ When tropomyosin was digested with carboxypeptidase, and the spectra of digested and undigested tropomyosin compared, there was a reduction in the narrow resonances corresponding to mobile residues at the C-terminus.⁵⁷ This mobility may be involved in reforming the coiled-coil structure once the tropomyosin polymerizes, since the heptapeptide repeats of the hydrophobic residues are intact in this region.

3.2.1 Interaction of Tropomyosin with Troponin

When polymerized tropomyosin was complexed with troponin, very little of the aromatic envelope of troponin was broadened.⁵⁸ This suggests a relatively flexible troponin complex when complexed with tropomyosin. Troponin binds to tropomyosin through the component of the troponin complex known as troponin T (TnT) which increases the head-to-tail polymerization of tropomyosin. In particular, the cyanogen bromide fragment CB1 (1–151) of TnT was able to invoke the same head-to-tail polymerization of tropomyosin observed with whole TnT.⁵⁹ Furthermore, studies have shown that CB1 binds close to the C-terminal end of tropomyosin and induces formation of a ternary complex with N- and C-terminal fragments of tropomyosin under conditions in which no interaction between these fragments could be detected.⁵⁹ Using a method similar to that previously described for measuring tropomyosin dynamics, namely observing histidine resonances, Brisson et al.⁵⁹ were able to show directly, by observing changes in the pH titration profile of histidine-153 of tropomyosin upon CB1 binding, that CB1 binds close to the C-terminal end of tropomyosin.

3.3 TnT

Troponin T is the largest, and least well studied (by NMR methods), component of the troponin complex which attaches the complex to tropomyosin. TnT has two phosphorylation sites, one at the N-terminal serine hydroxyl, and one at serine-194 in the C-terminal cyanogen bromide fragment CN4.⁶⁰

The ³¹P NMR spectrum of the N-terminal resonance revealed a narrow resonance which titrated in pH identically to free phosphoserine, indicating that the phosphorylation site is highly mobile.⁶¹ The same result was obtained with CB1⁶¹ and when TnT was bound to the rest of the troponin complex or nonpolymerizable tropomyosin or tropomyosin fragments.^{61,62} The role of phosphorylation in muscle seems to be correlated to the change in calcium sensitivity of the actomyosin ATPase.

3.4 TnI

TnI is a member of the troponin complex and is the inhibitory component of the ATPase activity of actomyosin. The calcium-dependent interaction between TnC and TnI is one of the key processes in the regulation of contraction in skeletal muscle. Residues 1–21 and 96–116 of TnI interact with TnC. The peptide 105–115 of TnI comprises the minimum sequence necessary for inhibition of the actomyosin ATPase activity. Experiments on binding troponin, tropomyosin, or actin to myosin S1(A1) have shown that the actin–S1(A1) interaction involving the N-terminal segment of A1 is calcium sensitive, and the presence of TnI alone markedly inhibits this interaction.⁶³

In cardiac muscle, phosphorylation of TnI occurs upon β -adrenergic stimulation, which is correlated to the change in calcium sensitivity of the actomyosin ATPase.⁶⁰ Bovine cardiac TnI phosphorylates at positions 23 and 24, the chemical shifts of which are altered by binding magnesium.⁶⁰

Structural studies on whole TnI have not been accomplished so far due to the size of TnI (21 kD). In order to study the interaction of TnI and TnC, the synthetic peptide 104–115 (TnIp), which is the minimum sequence necessary for the inhibition of the actomyosin ATPase activity, was synthesized and bound to TnC, and the stoichiometry and structure of this fragment was determined.^{64,65} It was found that TnIp bound to TnC with a stoichiometry of binding ratio of 1:1.⁶⁴ Using the transferred NOE experiment, the structure of the synthetic inhibitory peptide was determined when bound to TnC.⁶⁵ The structure revealed an amphiphilic helix distorted around the two central proline residues, bringing together the hydrophobic residues to form a hydrophobic pocket. The hydrophilic, basic residues extend from the opposite face of the peptide^{64,65} (Figure 3). The interaction of this peptide with TnC is discussed in the following section.

3.5 TnC

Troponin C (TnC) is the calcium-binding, regulatory protein of the troponin complex. TnC is an 18 kD protein utilizing four EF hand, helix–loop–helix motifs for binding calcium. Each calcium ion is bound by seven oxygen ligands, resulting in a pentagonal bipyramidal coordination geometry. The structure of two-calcium TnC has been solved to 0.2 nm resolution,^{66,67} revealing that TnC has two globular domains separated by a helical linker. Each domain contains two ion binding sites, the C-domain sites being the high-affinity calcium/magnesium binding sites with $K_{Ca} = 2 \times 10^7 \text{ M}^{-1}$ or $K_{Mg} = 2 \times 10^3 \text{ M}^{-1}$, and the N-domain sites being the low affinity calcium specific binding sites with a $K_{Ca} = 3 \times 10^5 \text{ M}^{-1}$.

Figure 3 Structure of the TnI peptide (104–115)⁶⁵ representing the minimum sequence necessary for the inhibition of the actomyosin ATPase activity. When bound to TnC, this peptide reveals a structure with an amphiphilic α -helix distorted around two central proline residues bringing together hydrophobic residues to form a hydrophobic pocket. Shown in yellow is the phenylalanine-106 residue; green indicates the hydrophobic leucine-111 and valine-114 residues. Shown in blue are the hydrophilic lysine and arginine residues which extend away from the hydrophobic pocket. The backbone is represented by the yellow solid ribbon

TnC is one of the proteins most studied by NMR. Indeed, its small size and homologous calcium binding sites have allowed numerous studies on whole TnC, fragments involving calcium binding, and the interaction between TnC and TnI or TnC and other drugs. Most of the work on TnC by NMR has been motivated by a need to understand the mechanism of the calcium switch that leads to the release of inhibition by TnI of the actomyosin interaction. In this portion of this article, we omit those studies involving other metals such as sodium, cadmium, and potassium binding to TnC, and concentrate on the calcium and magnesium binding, structural studies, and the interaction of TnC with other members of the troponin complex.

¹H NMR studies of TnC were first done by Seamon et al.⁶⁸ and Levine et al.⁶⁹ in 1977. ¹H NMR studies revealed that calcium induces a large folding of the backbone of the high affinity sites.^{68,69} Calcium binding to the low affinity sites did not alter the backbone of these sites significantly, but changed the hydrophobic interactions.⁶⁹ A comparison of magnesium and calcium binding to the C-domain demonstrated differences in the degree of backbone folding of this domain and altered interactions between hydrophobic residues when magnesium was bound.^{68,70} This led to the proposal that the important physiological sites were the N-terminal calcium specific sites and that the C-terminal sites are always filled with either calcium or magnesium. In 1988, Tsuda and coworkers,^{71,72} using high-resolution ¹H NMR techniques, also studied magnesium binding to TnC. They demonstrated that all calcium binding sites in the N- and C-domains bound calcium and magnesium, but magnesium binding to the N-domain did not induce a conformational change in the hydrophobic region.⁷² This was illustrated by resonances in both domains being influenced by magnesium binding. Studies

of TnC from different sources such as rabbit and pike revealed very similar properties.⁷³

Cardiac TnC (cTnC) has also been studied by NMR. This protein is quite different from skeletal TnC (sTnC) in the N-domain, where site I has lost the ability to bind calcium due to amino acid insertions and substitutions. Hincke et al.⁷⁴ observed spectral changes of cTnC that were similar in nature to changes of sTnC when calcium was bound. Another study⁷⁵ revealed that the structure of cTnC was extremely stable, as calcium addition could produce native-like features in 6M urea. Later studies on cTnC involved high-resolution two-dimensional NMR.^{76–78} Mutation of one of the residues in site III of whole cTnC, designed to prevent calcium binding to that site, resulted in a greater instability of the C-domain relative to a mutant at site IV.⁷⁹ A study of one-dimensional double quantum filtered COSY, and NOESY spectra illustrated that the tertiary fold of the C-domain of the site IV mutant, but not the site III mutant, was similar to wild type cTnC.⁷⁹ Calcium binding to site III was shown to be more crucial than calcium binding to site IV in stabilizing and folding the C-terminal domain of TnC⁷⁹ (see below, Shaw et al.^{80–83} and Kay et al.⁸⁴). Other studies^{77,78} on cTnC where aspartic acid-65 was replaced by alanine revealed that calcium binding to the N-domain was inhibited (the changes associated with formation of a β -sheet in the N-domain upon calcium binding were not observed) without significantly altering the solution conformation of the N-domain.⁷⁷ This mutant could not trigger muscle contraction.⁷⁷ These results illustrate the importance of aspartic acid-65 in maintaining the calcium binding site (see also Marsden et al.⁸⁵).

3.5.1 Fragments and Domains of TnC

There have been several studies on proteolytic or chemically cleaved and synthesized fragments of TnC. A CB9 fragment of 52 residues comprising the calcium binding site III of TnC (84–135),^{86,87} along with CB8 (46–77)⁸⁷ and TH2 (121–159),⁸⁷ were studied. CB8 was observed to have some secondary structure in the apo peptide while CB9 and TH2 exhibited very little secondary structure.⁸⁷ Calcium binding led to the spectral changes of CB9 and TH2, consistent with an increased restriction of backbone mobility and the adoption of a more compact form.^{86,87} CB9 was also shown to have a TnI interacting region. CB8 was unfolded and unperturbed upon calcium addition, indicating that other interactions may be responsible for its stabilization.⁸⁷

Studies on the C-terminal domain of TnC (TR2 C 89–159 and TR2E 101–159) have illustrated that there is a strong cooperativity in calcium binding to the C-domain.⁸⁸ As with native TnC, the difference between magnesium and calcium binding is a difference in backbone torsion angles and ring-plane orientations as a result of altered interhelical packing.⁸⁸ Removal of the N-terminal segment of TR2C to form TR2E resulted in perturbations of the hydrophobic region and reduced calcium affinity.⁸⁸ It was also shown that the affinity of the C-terminal binding site for calcium was reduced by cleavage of the linkage between the two calcium binding sites.⁸⁸

The use of synthetic peptides for the NMR study of TnC has gained widespread use. Gariépy et al.⁸⁹ synthesized several SCIII peptides of differing helical lengths. From the reduced calcium affinities of these peptides, they were able to show that

the N- and C-terminal helical regions stabilize the cation in the binding loop. Furthermore, the importance of metal charge and radius on the metal binding affinity was illustrated.¹²⁹ Other studies involved determining the essential residues comprising the calcium binding sites.^{85,90} Study of the calcium binding EF hands from many sources revealed that the invariant residues in the calcium binding loop are: aspartic acid-1 (+x), aspartic acid/asparagine-3 (+y), glycine-6, isoleucine-8, and glutamic acid-12 (−z).⁸⁵ It was shown that the helices surrounding the calcium binding loop account for 50% of the calcium binding affinity, while the interaction of the sites provides 43%.⁸⁵

The first NMR structure of TnC fragments was determined in 1990 by Shaw et al.⁸⁰ (Figure 4). A helix–loop–helix calcium binding peptide was synthesized which was unstructured without calcium but, upon calcium binding, formed a homodimer similar in tertiary structure to the C-domain of TnC (as determined by X-ray crystallography). The dimer exhibited an approximate two-fold rotational symmetry, with hydrophobic residues and a three-residue β -sheet at the interface of the two sites stabilizing the protein domain.^{80,83} When this dimer was mutated⁸¹ to include calcium ligands from site II, the K_d of calcium decreased slightly, but when all the residues in the calcium binding sites were mutated to site II residues the K_d decreased even further. These results suggest that differences in the coordinating ligands between sites II and III have very little effect on calcium affinity, and noncoordinating residues in site II are responsible for the low affinity of site II as compared to the high affinity of site III.

Kay et al.⁸⁴ also determined the structure of the 39 amino acid proteolytic fragment of rabbit skeletal TnC containing the fourth calcium binding site (TH2). Without calcium, TH2 adopts a random coil conformation. The dissociation constant of calcium for this heterodimer was found to be 1 M, indicating that a calcium/peptide ratio of 20:1 was needed to induce

Figure 4 Structure of the SCIII homodimer.^{80,81} Two peptides representing the helix–loop–helix calcium binding site III of TnC can adopt a fold similar to the crystal structure C-domain where residues 112, 113, and 114 of one peptide form an antiparallel β -sheet with the same residues on another peptide. The two monomers are represented in yellow and green; their approximate two-fold rotational symmetry is evident

dimer formation. Even though the calcium affinity was low, the structure of this homodimer was similar to the site III homodimer and the C-terminal domain of TnC.

When an equimolar mixture of 34-residue peptides representing SCIII and SCIV were mixed in the apo form, a ^1H NMR spectrum typical of a random coil conformation was observed.⁸² When calcium was added, however, a heterodimer resulted (which showed a ^1H NMR spectrum substantially different from either the apo or homodimer spectra) with a calcium affinity greater than that of the homodimer. The spectrum of the heterodimer was very similar to the spectrum of TR2C, indicating the heterodimer to be a good model of the C-domain of TnC.

Findlay and Sykes⁹¹ and Findlay et al.⁹² studied the apo TR1C structure of skeletal TnC (Figure 5). TR1C comprises helices A to D in the N-domain. They observed that the secondary structure of the two-calcium binding sites in the N-domain are different, as was observed in the crystal structure. The structures and orientation of helices A, B, and D and the β -sheet region are well defined and agree closely with that region in the X-ray structure. Helix C was determined to be well defined, but its orientation to the other helices was not. This questionable orientation was clarified in the apo-N-domain structure reported by Gagné et al.⁹³

3.5.2 Interaction of TnC with TnI

One of the first studies on delineating the interaction between TnC and TnI involved placing a paramagnetic spin label on cysteine-98 of rabbit skeletal TnC and studying the interaction of the TnC peptide CN4 (96–116) with a CN5 (1–21) peptide of TnI.⁹⁴ An interaction between these two peptides as well as between CN5 and whole TnC was observed.⁹⁴ Back-titration with EGTA resulted in a loss of the paramagnetic broadening of CN5 with no alteration of the signals of CN4, indicating a calcium sensitivity of CN5 binding to TnC.⁹⁴

TnI binding to TR2C⁸⁸ was shown to alter the relative dispositions of several methyl groups with respect to the

Figure 5 Structure of apo TR1 C (residues 12 to 87 of turkey skeletal TnC).^{91,92} The size and orientation of helices A–D as well as the β -sheet region of this average structure are similar to the crystal structure

aromatic rings, while retaining the overall structural features of the tertiary fold of TnC, and reduce the off rate of calcium in the complex.

A TnI peptide (TnIp), corresponding to the region of TnI representing the minimum sequence necessary for the inhibition of actomyosin ATPase activity (TnI(104–115)–NH₂), was synthesized.⁹⁵ A perturbation of the aliphatic, aromatic, and charged residues upon interaction of TnIp with TnC was observed.⁹⁵ Slupsky et al.⁹⁶ studied TnIp when it was complexed with TnC and with a site III/site IV heterodimer representing the C-domain of TnC. Similar changes in the C-terminal aromatic envelope, in both TnC and the heterodimer were observed, suggesting that the heterodimer is a good model for the C-terminal domain of TnC and illustrating that three relatively unstructured peptides can bind an ion and fold to mimic a larger system. Slupsky and Sykes⁹⁷ subsequently formulated a model for the binding of this TnI peptide to the C-terminal domain of TnC based on the NMR structure of calmodulin binding of the MLCK peptide (Figure 6). Tsuda et al.⁹⁸ also studied the CN4 fragment of TnI (96–116) binding to Ca₄TnC, and observed a change in chemical shift of C-terminal as well as N-terminal residues. This peptide was able to increase the transition temperature of the N-domain, and thus was thought to interact with both domains. When this peptide was added to Mg₄TnC, however, only C-terminal residues were perturbed.⁹⁸

Figure 6 Ribbon model of the interaction between the C-domain of TnC and TnI(104–115) (TnIp). (Green) Hydrophobic residues; (red/acidic pink/purple) polar residues; (blue) basic residues. The TnIp hydrophobic residues face in toward the hydrophobic pocket of the C-terminal domain of TnC. The TnIp/TnC complex model was obtained by overlaying TnIp and TnC onto the CaM–MLCK peptide structure¹²⁸ to obtain a minimum root-mean-square deviation (rmsd). The relative orientation of TnIp in the complex was subsequently optimized under energy criteria using a combined Monte Carlo/energy minimization approach. Comparison of the backbone atoms of the calmodulin/MLCK complex (203, 204, 205, 206 of MLCK and 98, 99, 100, 101 of CaM) with the TnC/TnIp complex (105, 106, 107, 108 of TnIp and 111, 112, 113, 114 of TnC) produced a rmsd of 1.45

3.5.3 Interaction of TnC with Drugs

MacLachlan et al.⁹⁹ and Reid et al.¹⁰⁰ studied the binding of drugs to TnC. Bepridil binding to cTnC was able to alter resonances of the N-domain and reduce the rate of calcium release from the low affinity site only.⁹⁹ Binding of calmidazolium to skeletal TnC was found¹⁰⁰ to induce changes to both domains. The binding stoichiometry of both bepridil and calmidazolium to TnC was found to be 1:1.

Tsuda and Hikichi¹⁰¹ studied mastoparan binding to rabbit skeletal TnC in its apo, calcium saturated, and half saturated forms. Titration of apo TnC with mastoparan revealed mastoparan interacting with the N-domain. Titration of Ca₄TnC with mastoparan revealed an interaction of mastoparan with the C-terminal domain. Titration of Ca₂TnC with mastoparan revealed an interaction with both the N- and C-domains of TnC. In each TnC state, mastoparan broadened resonances in the hydrophobic cluster. The N-domain stability increased when one molar equivalent of mastoparan was bound to Ca₂TnC or Ca₄TnC, suggesting a mastoparan-induced interaction between the N- and C-domains of TnC. The downfield shifted C^αH resonances were moved upfield upon mastoparan binding, indicating an increased distance between the two strands of the β -sheet. The affinity of mastoparan for the C-domain of TnC was stronger than that for the N-domain.¹⁰¹

4 OTHER PROTEINS OF THE MUSCLE

4.1 Calsequestrin

Only one paper has appeared describing NMR studies of this member of the SR.¹⁰² Calsequestrin is a highly acidic protein of molecular weight 44 kDa, and can bind up to 50 calcium molecules per molecule of protein with a binding constant of 1 mM. The function of calsequestrin is to act as a calcium buffer, effectively to lower the free calcium concentration within the SR. In the absence of calcium, calsequestrin appeared to be largely in the random coil form. Calcium binding to calsequestrin caused an increase in α -helix content to 35% and a broadening and loss of intensity in the aromatic and aliphatic regions of the spectrum by about 70%.¹⁰² The decrease in intensity could be due to a compaction of the molecule, as determined in hydrodynamic studies where the protein was largely extended in the absence of calcium, but more compact in the presence of calcium.

4.2 Dystrophin

Dystrophin is a recently discovered multidomain (MW 427 kDa) protein, the lack of which is associated with muscular dystrophies.¹⁰³ Dystrophin is rod-like in shape and has been found associated with the membrane of the muscle cell. Since ion permeability is increased in dystrophic muscle cells, dystrophin must function in muscle membrane structure.¹⁰³ The N-terminal sequence of dystrophin is homologous to α -actinin, and thus there have been two recent studies employing NMR to determine the interaction between dystrophin and actin.^{103,104} Synthetic peptides corresponding to regions of the dystrophin molecule that may interact with F-actin

were studied. Peptides comprising residues 1–32 and 10–32 interacted with actin.^{103,104} Furthermore, it was shown that the peptide 10–32 did not compete with TnI for binding to actin, nor did it have an effect on the inhibition of the magnesium-activated ATPase of actomyosin by TnI. Another peptide, 3429–3220, did not interact with F-actin at all.^{103,104} Thus it was concluded that the region represented by residues 10–32 of dystrophin interacts with actin.

4.3 Parvalbumin

Parvalbumin is a protein found in the cytosol of muscle cells and is thought to act as a one-way calcium messenger, being particularly important in cold-blooded animals such as fish and amphibians. The crystallographic structure of parvalbumin¹⁰⁵ indicates that each of its two calcium binding domains has the EF hand structure. It is of interest to note that all calcium binding proteins give similar assigned NMR fingerprints for each pair of two hands, indicating that the hands are similar.¹⁰⁶ Parvalbumins are of low molecular weight (approximately 12 kDa), and are characterized by a high calcium ion affinity (approximately 10^8 M^{-1}). The polypeptide chain is arranged in six helical fragments (A–F) whose spatial organization reveals a core of hydrophobic residues, much like TnC. Comparison of the amino acid sequences from different species indicates the presence of two distinct phylogenetic lineages termed α (pI 5.0) and β (pI 4.1).¹⁰⁷

Parvalbumin has been studied using ^{13}C NMR^{108–111} and ^{19}F NMR^{112,113} with a fluorine label attached to the cysteine-18 residue. ^{13}C NMR revealed significant internal motional freedom of the phenylalanine residues in the calcium-loaded parvalbumin.¹¹⁰ ^{19}F NMR of labeled parvalbumin revealed a change from exposure to solvent in the calcium free state to buried in the calcium saturated state,¹¹³ resulting from changes in the relative disposition of the helices upon calcium binding. This was also shown using ^1H NMR¹¹⁴ for several parvalbumins.

Removal of calcium ions from parvalbumin leads to a structure similar to that obtained by chemical or thermal denaturations shown by ^1H NMR.¹¹⁵ The calcium binding affinity of parvalbumin was determined to be dependent on the tertiary structure.¹¹⁶ The tertiary structure was found to vary reversibly between a compact PaCa₂ structure and a more expanded Pa(0) structure.¹¹⁶ Observation of amide proton exchange rates of residues located in calcium-loaded parvalbumin revealed that residues in the A–B helices exchanged faster than residues in the C–D and E–F helices for PaCa₂.¹¹⁷ This difference did not exist for PaMg₂, where faster exchange rates were observed over all of the sequence.¹¹⁷ The NOE networks were conserved between the calcium and magnesium loaded forms of parvalbumin, indicating that the structures of the two are very similar. Other studies involving rat apo and metal-bound α -parvalbumin also showed similar structures upon binding of different ions.¹¹⁸ The thermal stability was shown to decrease upon complexation with ions other than calcium.¹¹⁸

The binding of other metal ions to parvalbumin and possible differences of ion binding in the different isoforms of parvalbumin was studied by Lee and Sykes¹¹⁹ and Lee et al.¹²⁰ Their approach involved determining the orientation and principal elements of the magnetic susceptibility tensor

of the protein bound Yb³⁺ ion. This resulted in agreement between a calculated spectrum based on the X-ray structure of parvalbumin and an observed spectrum, demonstrating the utility of NMR in determining subtle differences in structure upon ion binding. Other studies of the metal ion binding site involved using NOE build-up curves to determine differences in the spin diffusion of residues in the calcium binding loop and relating this to slight calcium binding differences between parvalbumins.¹²¹

The three-dimensional structure of pike pI 5.0 parvalbumin (a member of the α series) has been determined using two-dimensional NMR techniques and DISGEO (distance geometry).^{122,123} The overall shape of this parvalbumin is a compact organization of polypeptide chains with six helical domains labeled A–F, all helices (except D) being in a regular α -helix. The six helices displayed the characteristic spatial organization of parvalbumin, with A and B in an antiparallel arrangement, and C and D and E and F in a perpendicular arrangement, the CD and EF helices coming in close contact to form a short antiparallel β -sheet at the level of residues 57, 58, and 59, and 96, 97 and 98. The structure of α -parvalbumin was shown to be similar to the crystal structure¹⁰⁵ of the β -parvalbumins in the folding of its polypeptide chain, the difference being that α -parvalbumin has one extra residue at the C-terminal end of the F helix.¹²² It turns out that this lengthening of the helix is a general feature of α -parvalbumins, resulting in an enhanced conformational stability due to this C-terminal region coming in close contact with the B helix. Indeed, a NOE was observed between the C-terminal alanine 109 of the F helix and lysine 27 of the B helix.¹²² It was also shown¹²⁴ that the protonation/deprotonation of histidine 25 and histidine 106 causes a conformational change in the B helix/F helix region.

With the advent of homonuclear three-dimensional techniques such as the three-dimensional HOHAHA NOE experiment,^{125,126} better structures of parvalbumin will be determined due to less resonance overlap and better resolution of NOE data.

5 FUTURE WORK IN MUSCLE RESEARCH BY NMR

NMR has always been an extremely useful tool in the field of muscle research. It has helped, and will continue to help, in defining the interaction sites between actin monomers, actin and myosin, actin and tropomyosin, tropomyosin and troponin, as well as interactions within the troponin complex. NMR has also been useful in determining the kinetics of transitions and binding constants. With the advent of the new three- and four-dimensional NMR techniques, as well as techniques of protein enrichment with ^{15}N , ^{13}C , and ^2H isotopes, structural studies of muscle proteins are now possible. The muscle proteins accessible using these techniques include TnC, TnI, the essential and regulatory light chains, as well as actin (TnT may be too difficult due to its low solubility). Peptides representing regions of interaction between these proteins may also be used to probe interaction sites. Indeed, our group has nearly completed the solution structure of calcium-loaded TnC,^{130,131} and the apo and calcium loaded N-domain of TnC,^{93,127} and is currently investigating the interaction of domains of TnC with fragments of TnI.

1 INTRODUCTION

Crucial biological processes central to the molecular biology of animals and plants entail interactions of proteins and other nucleic acids with double helical deoxyribonucleic acid (DNA). These interactions can involve recognition of subtle structural variations in the DNA double helix that are sequence-dependent. Furthermore, these structural details may also direct mutagen or drug recognition. A detailed understanding of these processes requires the determination of biologically relevant structures. With subtle sequence-dependent structural features, a meaningful structure for a double helix may compel a high-precision structure. Analysis of X-ray diffraction from oligonucleotides in single crystals has demonstrated a significant sequence-dependent heterogeneity of DNA structure. However, single crystal X-ray diffraction has serious problems. Perhaps the most readily acknowledged problem has been that crystallizing DNA fragments does not generally leave them in the B form, i.e., the form in which they are nearly always found in solution. Even in those cases where the B form is obtained for a crystal, there is concern about the influence of crystal packing forces on the DNA structure. In a couple of different cases now, crystallization of a B DNA duplex into two different crystalline types has had a substantial impact upon many local structure parameters.

Nuclear magnetic resonance has recently provided an option. The methodology for determination of structures with sufficient resolution via NMR has not been easily achieved, but the ability to determine an accurate, high-precision structure of nearly any DNA double helix of length less than 15 base pairs (bp) is now possible if sufficient care and effort are expended. Before resorting to the relatively troublesome task of 'determining a structure', however, we should acknowledge that some insight into toxicologic, pharmacologic, or biological function can often be derived from NMR spectral data without resorting to real structure determination.^{1,2} For example, it can be quite useful to discover what part of a DNA is interacting with a ligand moiety. This can be learned from a relatively

small amount of experimental data, e.g., from just a few NOE contacts. One can even model a chemically reasonable structure from these small amounts of data; but this does not constitute structure determination.

The structure of any molecule can be determined with a sufficient number of structural restraints, e.g., internuclear distances and bond torsion angles, in conjunction with holonomic constraints of bond lengths, bond angles, and steric limitations. Nuclear magnetic resonance, in conjunction with appropriate computational algorithms, has become the method of choice for determination of high-precision solution structures. Multidimensional NMR has the capability of yielding interproton distances and bond torsion angles as experimental structural restraints.³⁻⁶ These experimental structural restraints are used with algorithms, such as distance geometry (DG) and restrained molecular dynamics (rMD), which search conformational space to define all structures consistent with the experimental restraints. If these resulting structures are closely related and there is confidence that pertinent parts of conformational space have not been neglected, it is concluded that the structure has been determined. It is preferable that the array of structures generated by the search algorithms be large enough to map out the conformational space, which will accommodate all available experimental data.

Our ability to determine solution structures of a DNA duplex by NMR is limited by the quantity, quality, and distribution of distance and torsion angle restraints that can be extracted from the NMR data. The problem is exacerbated by degeneracy in secondary structure, lack of tertiary structure, and monotony of monomers. Further complications may ensue from limited conformational flexibility. In spite of these obstacles, high-precision structures can be determined. Higher 'resolution' can be achieved with more structural restraints and with more accurate structural restraints. Techniques used to establish these restraints and to assess structure are constantly improving.

In the following discussion, I will discuss the current state-of-the-art in the methodology to determine high-resolution NMR structures, with a particular emphasis on DNA duplexes. This discussion will include suggestions on particular methodology to be employed, a mention of some pitfalls and complications, and how to assess the structures determined.

2 STRUCTURE DETERMINATION

There has never been a consensus on the exact methodology to use for determining molecular structure via NMR; basically, however, NMR data must be acquired that permit assignment of resonances and which can be (semi)quantitatively related to the local structure. A search of conformational space must be made in an attempt to satisfy simultaneously all geometric requirements imposed by the holonomic constraints of atom connectivities, bond lengths and bond angles (and, in the case of rMD, energetics), as well as all the experimental NMR structural data. The procedure should reveal what structures are compatible with the available data. It is intuitively clear that more structural data will generally lead to a more closely related family of compatible structures, i.e., to a better defined or higher 'resolution' structure.

Unlike proteins, where assignment of resonances is often the bottleneck in structure determination, making proton

resonance assignments in a DNA duplex is fairly quick and straightforward.² All structures determined to date have utilized structural restraints from NOE cross peaks. Some structures have also utilized torsion angle restraints from the oligonucleotide backbone or sugar ring. However, the manner of determining distance and torsion angle restraints and the use of these data in structure determination has varied with time and from laboratory to laboratory. As the quality of the structure derived depends on the structural restraints and the structure refinement algorithms, some description of these topics follows.

2.1 Distance Restraints

The intensities of the cross peaks in a two-dimensional (2D) NOE spectrum are related to the distances between protons, which are in close spatial proximity ($<5\text{--}6\text{ \AA}$) in a structure and can be used to estimate those distances. In principle, we might anticipate that accurate cross-peak intensities would be desired in order to obtain accurate distances. However, obtaining intensities accurately reflecting the interproton distance generally requires that (a) the pulse repetition time (TR) of the experiment be long compared with the longest proton T_1 value, i.e., for relaxation to be nearly complete, (b) contributions to the cross peaks from multiple quantum coherences must be minimal, (c) good, flat base planes in the well-digitized spectra must be produced to enable good integration, and (d) peak overlap must be minimal (or very reliable deconvolution software must be available). Note that these requirements are not extreme. For example, if we arbitrarily find an error of 5% in measurement of the interproton distance r acceptable, we could tolerate an error in cross peak intensity of about 35%. (This assumes only the first order relationship that cross-peak intensity $\propto r^{-6}$, see below.) Other NMR laboratories typically use a TR of $\leq 2\text{ s}$, which would alone decrease intensities for typical DNA duplexes by 25–50% for most cross peaks, and by up to 90% for those entailing adenine H-2 protons. I point out that our laboratory has always used a TR of 8–12 s.

The effect of cross relaxation between two neighboring protons during the mixing time period τ_m of the 2D NOE experiment is to transfer magnetization between them. The efficiency of this transfer depends on the distance between the two protons and upon the rate of molecular motion. With transfer of magnetization, the cross-peak intensities in the spectrum will be modified. Consequently, the cross-peak intensities have structural information, i.e., distances, embedded in them. In interesting molecules, the two protons giving rise to a particular cross peak are not the only protons in the molecule. Rather, they belong to an array of all protons in the molecular structure which, in principle, experience dipole–dipole interactions with all the others. So cross relaxation between the two protons is part of a coupled relaxation network. There are different methods of analyzing 2D NOE spectra to obtain internuclear distances. The commonly employed two-spin or isolated spin pair approximation (ISPA) can be used:

$$r_{ij} = r_{\text{ref}} \left(\frac{a_{\text{ref}}}{a_{ij}} \right)^{1/6} \quad (1)$$

where r_{ij} is the interproton distance to be estimated and a_{ij} is the corresponding 2D NOE cross-peak intensity, while r_{ref} and a_{ref} are, respectively, a known interproton distance and its cross-peak intensity. This equation derives from truncation after the linear term of the Taylor series expansion of the complete rate expression accounting for all proton dipole–dipole interactions:⁷

$$\mathbf{a}(\tau_m) = e^{-\mathbf{R}\tau_m} \approx \mathbf{1} - \mathbf{R}\tau_m + \frac{1}{2}\mathbf{R}^2\tau_m^2 - \dots + \frac{(-1)^n}{n!}\mathbf{R}^n\tau_m^n + \dots \quad (2)$$

where $\mathbf{a}$ is the matrix of 2D NOE intensities, $\mathbf{R}$ is the matrix describing the complete dipole–dipole relaxation network, and τ_m is the mixing time for the experiment. The truncation is valid in the limit of short mixing time τ_m . The elements of the relaxation matrix $\mathbf{R}$ depend on spin-state transition probabilities, written below as zero-, single-, and double-quantum transition probabilities W_m^{ij} , as follows:

$$R_{ii} = 2(n_i - 1)(W_1^{ii} + W_2^{ii}) + \sum_{j \neq i} n_j (W_0^{ij} + 2W_1^{ij} + W_2^{ij}) + R_{li} \quad (3a)$$

$$R_{ij} = n_i (W_2^{ij} - W_0^{ij}) \quad (3b)$$

Here n_i is the number of equivalent spins in a group such as a methyl rotor. For a rigid molecule undergoing isotropic random reorientation with correlation time τ_c , the following equations for transition probabilities hold:

$$W_0^{ij} = \frac{q\tau_c}{r_{ij}^6} \quad W_1^{ij} = 1.5 \frac{q\tau_c}{r_{ij}^6} \frac{1}{1 + (\omega\tau_c)^2} \\ W_2^{ij} = 6 \frac{q\tau_c}{r_{ij}^6} \frac{1}{1 + 4(\omega\tau_c)^2} \quad (4)$$

where ω is the Larmor frequency of the protons, $q = 0.1\gamma^4\hbar^2$ and γ is the proton gyromagnetic ratio. The term R_{li} represents external sources of relaxation such as paramagnetic impurities. Spectral densities more complicated than simple isotropic tumbling can be readily accommodated.^{8,9} Truncation of the series expansion of equation (2) to the first term linear in $\mathbf{R}$ is valid if τ_m is sufficiently short, which is equivalent to assuming that each cross-peak intensity depends only on the cross-relaxation rate between the two pertaining protons, i.e., ISPA. ISPA can lead to sizable systematic as well as random distance errors due to the multispin effects commonly called ‘spin diffusion’.^{8,10–12} The general method of assessing the impact of spin diffusion has been to obtain 2D NOE buildup curves, i.e., cross-peak intensities as a function of mixing time. Spin diffusion is usually considered to be negligible if the buildup is initially linear, i.e., in the short mixing time limit. This assumption, however, is not good at mixing times commonly employed.^{10,13} For example, for mixing times generally accepted as being sufficiently short (i.e., 50–100 ms) and not including internal motions, ISPA can result in systematic errors of 45–80% in distances over 3.5 Å, a range which is quite important in defining molecular structure. Limiting analysis to 2D NOE spectra with short mixing times

also yields cross peaks with a lower signal-to-noise ratio and is inconsistent with our wish to eliminate spectral contributions from zero quantum coherence.

2.1.1 Complete Relaxation Matrix Analysis

Complete relaxation matrix analysis of proton homonuclear 2D NOE spectra enables many accurate interproton distances to be calculated by accounting for all dipole–dipole interactions, thereby obviating ‘spin diffusion’ effects.^{8,12} For this we utilize linear algebra and the simplifications that arise from working with the characteristic eigenvalues and eigenvectors of a matrix.⁸ The rate matrix $\mathbf{R}$ can be represented by a product of matrices:

$$\mathbf{R} = \boldsymbol{\chi} \boldsymbol{\lambda} \boldsymbol{\chi}^T \quad (5)$$

where $\boldsymbol{\chi}$ is the unitary matrix of orthonormal eigenvectors ($\boldsymbol{\chi}^{-1} = \boldsymbol{\chi}^T$), and $\boldsymbol{\lambda}$ is the diagonal matrix of eigenvalues. Since $\boldsymbol{\lambda}$ is diagonal,

$$\mathbf{a} = \boldsymbol{\chi} e^{-\lambda \tau_m} \boldsymbol{\chi}^{-1} \quad (6)$$

We have developed the program CORMA (for Complete Relaxation Matrix Analysis) for calculating NOE cross-peak intensities from either interproton distances or atomic coordinates.^{8,10} Such calculation of 2D NOE peak intensities (intensity matrix $\mathbf{a}$) from a model structure is often called ‘back calculation’.

Instead of simply comparing model structures, we prefer to determine a structure, so we need structural restraints. The most efficient techniques for calculating accurate distances entail an iterative approach.^{10,14–16} The MARDIGRAS algorithm permits the determination of a large number of accurate distance restraints and aids in individually setting bounds for those distances. It may be apparent from the above equations that we should be able to calculate distances directly from intensities, i.e., the reverse of the CORMA calculation outlined above. The matrix of experimental intensities at time τ_m , however, will generally be incomplete for biopolymers due to experimental limitations such as resolution (i.e., peak overlap) and (realistic) signal-to-noise ratio. As a consequence, the corresponding relaxation matrix does not represent the spatial arrangement of protons leading to the intensities: A direct back calculation of $\mathbf{R}$ will therefore fail to yield accurate, unbiased distances.^{10,11} The incomplete experimental intensity matrix can be augmented with intensities calculated for a model structure to form a hybrid intensity matrix.^{14–16} In an iterative fashion, the relaxation rate matrix is made internally self-consistent. As a consequence, distances emanating from the self-consistent relaxation rate matrix will not be biased. An important aspect of the MARDIGRAS algorithm is that all intensities are used to obtain all distances simultaneously, i.e., the entire cross-relaxation network is employed; this is in distinct contrast to the old paradigm of a one-to-one mapping of intensities and distances.

Recent improvements in MARDIGRAS account for the presence of explicit molecular motions⁹ or molecular motions implied by order parameters¹⁷ and incorporate effects of exchange with bulk water in the case of exchangeable protons.¹⁸ Due to exchange of imino and amino protons of nucleic acid duplexes with bulk water, the intensity of 2D

NOE cross peaks involving these exchangeable protons can be strongly altered (see below). Without taking such exchange into account, calculation of distances to exchangeable protons is risky. However, the additional structural information from using such distances is extremely valuable.

Any method used for calculating interproton distances from NOE data requires an estimate of the correlation time. In general, an isotropic correlation time is assumed for the overall tumbling of the DNA duplex; this assumption is reasonable up to a length of approx. 14 base pairs. Calculations using a cylindrical model have demonstrated that errors in interproton distances, which are dependent on interproton vector orientation, can result as the length-to-diameter ratio of the DNA ‘cylinder’ increases.¹⁹ We have incorporated the capability of utilizing overall anisotropic tumbling motions in MARDIGRAS calculations.¹⁷ For a trisdecamer (13 bp), the hydrated length-to-radius ratio can be calculated to be about 2.2, based on a hydrated diameter of $20.5 \pm 1.0 \text{ \AA}$ found for a couple of oligonucleotide duplexes,²⁰ and a rise per base pair of 3.4 to 3.5 $\text{\AA}$. This cylindrical ratio of 2.2 corresponds to a ratio of 2.4 in the ratio of long-axis versus short-axis tumbling.^{20,21} (The ratio is even smaller if one uses a value for the hydrated radius of 24–25 $\text{\AA}$ which is obtained from classical DNA hydrodynamics studies.) A ratio of 2.4 in the tumbling rate of a cylinder, compared with isotropic tumbling, has a negligible effect (<3%) on the values of distances calculated with either the MARDIGRAS algorithm or with other distance calculation procedures.^{19,22} Consequently, overall molecular tumbling can be considered to be effectively isotropic and well-approximated by a single correlation time. The correlation time of the duplex can be estimated from experimentally measured T_1 and T_2 relaxation times for individual resolved protons.²³

2.1.2 Distance Restraint Bounds

To search conformational space to find structures consistent with our experimental data, we need an estimate of the accuracy of our distance restraints. In particular, they are needed for setting bounds in distance geometry or flat-well size in rMD calculations. Most structural studies have utilized ISPA to estimate interproton distances, but estimates of the error, reflected by the upper and lower bounds assigned, vary widely throughout the literature. Tighter distance bounds (smaller error bars) lead to a higher resolution structure. But distance bounds made tighter than warranted by experimental accuracy mislead to a highly defined (small atomic root-mean-square deviation, RMSD) but incorrect structure.²⁴ So we wish bounds to be as tight as possible but not so tight that the real distance can lie outside the bounds.

More accurate distances available via MARDIGRAS minimize the possibility of an estimated distance lying outside the bounds. MARDIGRAS can also aid our choice of bounds, set individually for each proton pair.

1. The ‘error bar’ for the distance between two nuclei can be estimated from the fit of the corresponding element of the converged MARDIGRAS intensity matrix with the experimental cross-peak intensity, using as a minimum the error dictated by the experimental noise level.¹⁶
2. We have found MARDIGRAS to be surprisingly robust, generating a largely correct set of distances independent

- of the starting model used in the iterative process.^{15,16} However, there are some distance variations with starting structure; this variation can also aid our choice of bounds.
- Distances are determined from a single 2D NOE spectrum using MARDIGRAS, rather than using buildup curves constructed from a set of spectra at several mixing times. It is still desirable to obtain spectra at a few different mixing times. Depending on the internuclear distance and proton environment, different mixing times will be optimum for different proton pairs. This enables distances determined independently from spectra acquired at different mixing times to be compared. Of course, the range of distance values measured from different spectra for any given proton pair can aid in the choice of bounds.
 - MARDIGRAS calculates bounds for distances to protons undergoing motional or overlap averaging, i.e., methyl, methylene, and aromatic protons.⁹ As a consequence of iteration, MARDIGRAS converges to an internally consistent, relaxation rate matrix (and equivalently, a 2D NOE intensity matrix) in good agreement with experimental spectra. Distances are calculated from the individual cross-relaxation rates. Distances entailing protons averaged by motion or spectral overlap may be in serious error if the averaging is ignored. The cross-relaxation rates in these cases will depend on orientation as well as distance. MARDIGRAS does a second level of iteration, varying the orientation and distances of all dipole-dipole interactions to find the best fit.⁹ Most importantly, however, MARDIGRAS lists the distances corresponding to the worst-case geometries, enabling upper and lower bounds to be set for distances involving protons averaged by either overlap or internal motions.
 - Chemical exchange can alter cross-peak intensities,^{25–27} leading to inaccurate distances. Cross peaks entailing exchangeable protons in biopolymers (e.g., imino, amino, amide) depend on the exchange rate with bulk water. Exchange effects are included in the MARDIGRAS algorithm, with exchange involving bulk water emphasized.¹⁸ To be significant, exchange rates with water must be $>1\text{ s}^{-1}$. Ignoring these effects will lead to overestimated distances. If the exchange rate is not known, it may still be possible to estimate an upper limit to the exchange rate: Use of this upper limit to exchange in the calculation can lead to a lower distance bound estimate.^{18,28,29} In recent work, we measured imino proton exchange rates using the method of Adams and Lerner,³⁰ so the exchange rate values can be incorporated into MARDIGRAS calculations yielding more accurate distances involving imino protons.³¹

2.2 Torsion Angle Restraints

Bond torsion angles can be determined using Karplus correlations with vicinal coupling constants, which can be derived from various correlation spectroscopic techniques, e.g., EASY, PCOSY and double quantum filtered COSY (2QF-COSY).^{32–34} In principle, these should enable us to determine pucker conformation in deoxyribose rings. Broad lines have prevented direct analysis of all coupling constants in DNA oligomers greater than about 8 bp in length. Consequently, most laboratories determine only those that can be readily measured, or determine sums of coupling constants, e.g.,

$\Sigma\text{H-2}'$, the sum of all coupling constants involving the H-2' proton of a deoxyribose ring. We have found that limiting analysis to these can leave ambiguities, but fitting of experimental cross peaks to cross peaks simulated using the SPHINX/LINSHA program package³⁵ enables extraction of vicinal coupling constants and, subsequently, torsion angle restraints.^{36–38} A comparison of simulated and experimental 2QF-COSY cross peaks for couple of deoxyribose rings in a trisdecamer duplex is shown in Figure 1. The torsion angles for the deoxyribose rings are determined using a parameterization of the relationship between torsion angles and coupling constants.^{2,39,40} The major difficulty with this approach is in establishing the correct linewidth to be employed.^{31,37} However, the choice of linewidth can usually be constrained such that limits (bounds) on torsion angles describing sugar pucker can be made. An improvement in procedure was recently described: the 2QF-COSY simulations were augmented by extraction of explicit vicinal coupling constants between H-1' and the H-2'/H-2'' protons from ECOSY cross peaks.³¹

In studies of about 10 DNA duplexes, examining all scalar coupling-based cross peaks, we find that a single conformer will rarely account for all measured coupling constants, but reasonable fits are obtained with a two-state model representing a rapid interconversion between S- and N-type sugar puckers.⁴¹ Unrestrained molecular dynamics calculations in our laboratory and elsewhere suggest that more than two sugar pucker states may exist, and recent molecular dynamics calculations using exponentially weighted, time-averaged restraints also indicate that sugar puckers other than standard N- and S-states are significantly populated for some nucleotides in a sequence.^{42,43} To employ the simplest model to account for the data, in recent years we have utilized the two-state model. The pseudorotational phase angles of the major S- and minor N-conformers (P_S and P_N , respectively), as well as the relative populations and amplitudes of these conformers are typically derived. For nonterminal nucleotides, we generally find that the S conformer dominates, being populated 75–95% of the time; there are a few exceptions.

2.3 Structure Refinement from Restraints

With a sufficiently large number of well-distributed structural restraints, we can proceed to generate a structure.⁴⁴ Ideally, we should try to determine all structures that will satisfy the experimental structural restraints, so that the accessible conformational space can be mapped out. In some sense, this gives us a fuzzy picture of the structure. With more restraints, more accurate restraints, and tighter (but not unreasonable) bounds, the structural picture becomes sharper. Methods entailing systematic searches of conformational space have been advocated, but they are computationally too expensive at present for biopolymers. So a guided search of conformational space is preferred at present. While it is possible simultaneously to refine restraints and structure iteratively, we advocate separating the restraint determination step and the structure generation step. This should diminish any possibility of being trapped in a local energy minimum in the vicinity of early iteration structures which are trying to satisfy inaccurate restraints. Also, individual assessment of the bounds for each structural restraint can be determined and then used in the structure refinement procedure.

Figure 1 Comparison of experimental (solid boxes) and simulated (broken boxes) double quantum filtered COSY cross peaks for some representative deoxyribose rings in d(AGCTTGCCTTGAG) · d(CTCAAGGCAAGCT). Negative components are shaded for experimental peaks and dashed for simulated peaks. Note that the experimental cross peaks displayed in some cases also exhibit partial cross peaks from other nearby or overlapping cross peaks

Distance geometry and restrained molecular dynamics (also called simulated annealing) calculations are commonly used for structure generation and refinement. Both entail two key facets: (a) a search of conformational space to yield a structure consistent with all restraints, and (b) optimization of any resulting structure. Although distance geometry has been employed, there is an apparent consensus among practitioners that for DNA duplex structure determination we should attempt to reconcile experimental structural restraints with energetic considerations, generally via restrained molecular dynamics simulations. Molecular dynamics simulations have been reviewed recently.^{45,46} It should be understood that an rMD simulation is not the same as a molecular dynamics (MD) simulation, which is generally concerned with following the molecular motions of a molecule over the femtosecond to nanosecond timescale. Rather, rMD uses the mathematics of MD to search conformational space. The kinetic energy in an MD simulation allows energy barriers of approximate amplitude kT to be crossed in a search for the global energetic minimum, which maintains a balance between maintenance of the 'classical' energy terms and the experimental restraints. In rMD, the potential energy is modified to incorporate experimental NMR restraints:

$$V_{\text{total}} = V_{\text{bond}} + V_{\text{angle}} + V_{\text{dihedral}} + V_{\text{van der Waals}} + V_{\text{coulomb}} + V_{\text{H bond}} + V_{\text{NOE}} + V_{\text{J coupling}} \quad (7)$$

The first five terms monitor the classical potential energy of the molecule. There may or may not be an explicit term used to maintain hydrogen bonds. The final two terms serve as penalty functions, monitoring the NOE-derived distance restraints and scalar coupling-derived torsion angle restraints, respectively. Some studies have not incorporated torsion angle restraints, but all have utilized distance restraints. Different functional forms have been employed for these penalty functions; we employ a flat-well potential with quadratic boundaries beyond the experimental upper and lower distance bounds:

$$V_{\text{NOE}} = \sum_{\text{all NOEs}} \begin{cases} k_2(r - r_1)^2 & \text{when } r < r_1 \\ 0 & \text{when } r_1 \leq r \leq r_u \\ k_3(r - r_u)^2 & \text{when } r_u < r \\ 4k_2(r - r_u) & \text{when } r > r_u + 2.0 \end{cases} \quad (8)$$

where the lower (r_1) and the upper (r_u) bounds can be derived from MARDIGRAS (see above) to define the size of the flat-well width individually for each proton pair. Similarly, $V_{\text{J coupling}}$ can be defined. We currently use AMBER 4.1 for rMD simulations.⁴⁷

Whereas force constants to be used for the conventional energy terms are rather well established, such has not been the case for the experimental restraint energy terms. We have consequently examined the effects of changing the force constant for the restraint energy terms in some detail for four different DNA duplexes. While the apparently optimum value varies somewhat for the different duplexes, as long as the force constant is in the range $10\text{--}40 \text{ kcal mol}^{-1} \text{ \AA}^{-2}$ for simulations near 300 K, the exact value chosen is not a strong influence. On the basis of our experience, I would recommend that a value of $20 \text{ kcal mol}^{-1} \text{ \AA}^{-2}$ be utilized in the absence of an evaluation for any particular duplex. The force constant for torsion angle restraint violations should be 3–4 times larger

than that for distance restraint violations. Of course, in a simulated annealing protocol, where the temperature is raised, the force constants should be commensurately increased.

For rMD simulations, starting structures should be chosen in different regions of conformational space, e.g., A-DNA, B-DNA and possibly some other model structure. In addition, different random initial trajectories should be used for each starting structure. Newton's equations of motion are solved with the forces resulting from taking the derivative of the potential expressed in equation (7). In a successful simulation, a global energy minimum is achieved. Indeed, the same global minimum should be reached with all the different initial structures and different initial trajectories. In reality, the structures resulting from different simulations will not be identical, but they should be similar, i.e., with small atomic RMSD between the individual structures little bigger than atomic displacements from librational motions (approx. $0.5 \text{ \AA}$): generally $<1.0 \text{ \AA}$ is considered adequate. While structures resulting from the different trajectories are typically averaged and a 'final' structure reported, the envelope of individual structures, which appears as a 'fuzzy' structure, is perhaps a better representation. An example is shown in Figure 2.

There are methods other than DG and rMD for generating structures from NMR data, but there are few cases where different structure refinement methods have been independently applied to the same data set and the resulting structures compared. A Monte Carlo search in torsion angle space has been developed and results reported for one DNA octamer duplex.⁴⁸ Use of generalized helical parameters, rather than Cartesian coordinates, to define DNA conformation, increases efficiency by decreasing the number of parameters by an order of magnitude. Using an idealized geometry for the aromatic rings eliminates the small distortions sometimes observed with structures emanating from rMD due to the force field, permitting some distortion of bond angles and lengths in a compromise to fit the experimental restraints. Various different, simulated, annealing protocols were employed: The Metropolis Monte Carlo algorithm was used to generate the Boltzmann distribution of DNA structures at a series of different (increasing then decreasing) temperatures in each case. Convergence of final structures via restrained Monte Carlo (rMC) calculations is easily achieved from A-DNA and B-DNA (atomic RMSD $<0.3 \text{ \AA}$ for all rMC simulations) without use of torsion angle restraints. For rMD, it is difficult (but sometimes possible) to achieve convergence to a global minimum starting from A-DNA without torsion angle restraints. The structures resulting from rMC and rMD are in agreement (RMSD $<0.5 \text{ \AA}$ for all structures generated) despite the different force fields used and despite the fact that rMD utilized deoxyribose torsion angle restraints. The structures generated with rMC and rMD were both in reasonable accord with experimental 2D NOE peak intensities and with experimental scalar coupling data from 2QF-COSY spectra. Agreement with the scalar coupling data is particularly satisfying because those data were used in the rMD refinement but not the rMC refinement.

3 CRITERIA TO ASSESS THE QUALITY OF NMR-DERIVED STRUCTURES

It is common practice to cite the atomic RMSD (or variance) for a set of structures resulting from DG or rMD:

Figure 2 Ten superimposed structures of [d(AGCTTGCCTTGAG) · d(CTCAAGGCAAGCT)], a completely conserved sequence from the 3'-long terminal repeat of the HIV-1 genome. The structures are from 10 rMD simulations, each of 30-ps duration, five using A-DNA and five using B-DNA as starting structure, but each with a different initial trajectory. Convergence to an atomic RMSD of approx. 0.9 Å is achieved, compared with RMSD approx. 6.5 Å between the two different starting models, A-DNA and B-DNA. A total of 267 distance restraints (approx. 10 per nucleotide) and 130 torsion angle restraints (five per nucleotide) were employed

the lower the value, the better. Sometimes the RMSD is interpreted as an indicator of the accuracy of a structure, or at least the precision of a structure. It should be kept in mind, however, that it is really only a convenient means of assessing the extent to which the structures generated have converged, although it is useful in a semiquantitative sense, as the atomic RMSD is related to the 'resolution' of the structure derived. For example, the structure of the trisdecamer duplex shown in Figure 2 is relatively well restrained by the experimental structural restraints (approx. 10 distance restraints and five torsion angle restraints per nucleotide²⁸) but the spectral resolution of some DNA duplexes studied in our laboratory have permitted more restraints to be determined leading to structures with lower atomic RMSD values. For [d(GATGCAAATG) · d(CTACGTTTAC)], the inner eight base pairs of which comprise the octamer motif found in promoter and enhancer regions of immunoglobulin genes and are recognized by the POU domain of certain transcription factors, approx. 20 distance restraints and five torsion angle restraints per nucleotide were obtained.²⁹ Several rMD simulations

Figure 3 Influence of the fraction of experimental distance restraints utilized in rMD refinement on the structure of [d(GATGCAAATG) · d(CTACGTTTAC)]. The atomic rms difference between several structures refined against full and against partial data sets is shown as a function of the fraction of experimentally determined distance restraints randomly deleted from the restraints' list. The starting structure was energy-minimized B-DNA; the RMSD with none of the distances removed reflects the difference between independently refined structures using different initial velocities in the rMD procedure

resulted in a well-defined structure. With so many restraints available, it was possible to investigate the effect on the derived structure of randomly eliminating some of the distance restraints. As seen in Figure 3, randomly reducing the distance restraints to an average of ≥ 12 per residue has little effect on the final structure derived. As reflected in the atomic RMSD, however, fewer than about 12 distance restraints per residue apparently results in a less defined DNA structure. It should be noted though that with only 50% of the restraints, the experimental restraints still largely determine the structure; there is a difference of more than 5 Å RMSD between energy-minimized A- and B-DNA structures.

One should be cautious about comparing RMSD values from one study with another. In fact, one should be careful about trying to push the value too low. It is possible to make the RMSD smaller by various means, e.g., by using larger force constants for the restraint violation terms in rMD simulations, by inadequate sampling in DG calculations, and by choosing very tight restraint bounds. While we want the restraint bounds to be tight to improve resolution, restraint bounds made tighter than the experimental accuracy will result in a better RMSD and also lead to inaccuracies in the structure.²⁴

While it provides some insight, the atomic RMSD is definitely not a measure of accuracy and is only a modest descriptor of precision. Other criteria can be cited, however. For example, we can compare the final structure, or interim structures, with the experimental NMR data. In X-ray crystallography, an evaluation of the fit of a derived structure with the original electron densities via a residual index (*R* factor) is requisite for any published structure. Yet such a comparison of the derived structure with the original data is rarely done for NMR

structures. However, we can quantitatively compare calculated 2D NOE spectral intensities for any proposed molecular structure with the experimental intensities. We could use a residual index analogous to the crystallographic R factors:

$$R_1 = \frac{\sum_i |a_o^i - a_c^i|}{\sum_i (a_o^i)} \quad (9)$$

R_1 gives equal weighting to all deviations between observed and calculated intensities a_o and a_c , so stronger peaks (from shorter distances, i.e., <2.5 Å) will generally dominate. Consequently, we prefer a sixth-root residual index which scales roughly with atomic distances:^{12,24,49}

$$R_1^x = \frac{\sum_i |a_o^{1/6}(i) - a_c^{1/6}(i)|}{\sum_i a_o^{1/6}(i)} \quad (10)$$

R_1^x permits longer interactions, e.g., approx. 4 Å, to have a role in the calculated R factor. Longer distance restraints are most important in structure determination, so it would be good to have their input into assessing structure quality. It has been pointed out that R factors are, in principle, dependent on the sign of the errors between the model structure's intensities and the experimental data, so a quality factor (Q_1) was proposed.⁵⁰ We have subsequently incorporated this idea into the MARDIGRAS program which now reports the following Q factors in addition to R factors:

$$Q_1 = \frac{\sum_i |a_o^i - a_c^i|}{\sum_i (a_o^i) + \sum_i (a_c^i)} \quad Q_2 = \left[\frac{\sum_i (a_o^i - a_c^i)^2}{\sum_i (a_o^i)^2 + \sum_i (a_c^i)^2} \right]^{1/2} \quad (11)$$

$$Q_1^x = \frac{\sum_i |a_o^{1/6}(i) - a_c^{1/6}(i)|}{\sum_i a_o^{1/6}(i) + \sum_i a_c^{1/6}(i)}$$

$$Q_2^x = \left\{ \frac{\sum_i [a_o^{1/6}(i) - a_c^{1/6}(i)]^2}{\sum_i [a_o^{1/6}(i)]^2 + \sum_i [a_c^{1/6}(i)]^2} \right\}^{1/2} \quad (12)$$

Unlike X-ray crystallography, it is possible to define a subset of NOE cross peaks and calculate an R or Q factor pertaining to some particular aspect of the structure, e.g., interresidue vs. intraresidue, or one selected region of the molecule. Analysis is capable of indicating regions of good (or bad) fit between any model structure and the true solution structure.

In principle, we might wish to generate a structure with the lowest R factor possible. However, we should be prudent in our efforts to push an R factor to its lowest value. R factors are also of limited value when assessing the accuracy of a refined model. A small restraint set can be easily overfit to a low R value, although the structure is only poorly defined by the data. Other complications arise from the nonrandom nature of errors in experimental intensities and our limited knowledge of molecular motions. Although the exact nature of the molecular motions is not a strong determinant in the calculations of the 2D NOE intensities, motions can still influence the intensities.⁸ Therefore, lack of knowledge about internal motions will render the calculation of some intensities for the model structure inexact. However, using the approximation that all methyl motions are fast and all aromatic ring flips are slow

compared with the overall molecular tumbling rate in proteins, enables a quite reasonable approximation of the intensities and, consequently, a reasonable calculation of R or Q factors.⁹

Recently, a free R factor, R_1^{free} , has been proposed as a reliable and unbiased indicator for assessing X-ray crystal structures and NMR structures.⁵¹ In the case of NMR, R_1^{free} measures the fit of a model structure's NOE intensities to a randomly selected set of experimental NOE intensities that are not used in structure refinement: approx. 10% of the total are in the test set, the other 90% are used in structure refinement. This avoids any model bias in calculating the R value. It is to be expected that R_1^{free} will be larger than R_1 , since the test data were not used in structure generation. However, discounting noise in the data, if the test data are consistent with the structure determined, R_1^{free} should not be too much larger. The exact amount considered acceptable probably awaits more experience with real data. It might be pointed out that R_1^{free} is 50–100% larger than R_1 for the few proteins examined so far, and we found it to be 60% larger in one DNA decamer duplex. Note the total range of the X-ray R factor (with a maximum value of 0.83) is much more limited than an NMR R factor (with a maximum value of ∞).

Consistency of the final structure with scalar-coupling-based multidimensional NMR spectra may be assessed as well. For example, the RMSD between experimental and theoretical coupling constants can be calculated according to $J_{\text{rms}} = (1/N) \sqrt{\sum (J_{\text{exp}} - J_{\text{theor}})^2}$. The summation is over N , which constitutes all or any subset of the coupling constants.⁴⁸ Of course, this assumes that a well-parameterized Karplus relationship has been established between the dihedral angles and three-bond coupling constants.²

There are other criteria that depend on the method of refinement. A residual distance violation is the difference between a particular interproton distance in a structure and the closest of either the upper or lower bound. An evaluation of the structures resulting from distance geometry in terms of the violations (typically weighted according to σ^4) is standard practice. For structures resulting from rMD or rMC refinement, the restraints' violation energies ($V_{\text{NOE}} + V_{J_{\text{coupling}}}$) should be low, and the total of the other terms should not be too much greater than in the absence of the experimental restraints.

Naturally, any structure we generate should be consistent with any other experimental data available on the oligomer in solution. In principle, we can compare our structure with any available crystal structure. However, in the case of a DNA duplex, it is highly unlikely that a good diffracting crystal in anything other than A form, i.e., not comparable to a solution structure, can be obtained. We must even be careful about any B form crystal structure due to the influence of crystal packing forces (see above).

4 COMPLICATIONS FROM CONFORMATIONAL FLEXIBILITY

A serious attempt to determine structure in solution with high precision must be cognizant of the possibility of multiple conformers and molecular motions. First, we need to consider the effect of molecular motion on our ability to determine an accurate time-averaged structure: i.e., will internal motions lead to systematically biased

distances and distorted structures. Second, we would like to impose molecular motion information on the time-averaged structure and thus obtain a dynamic picture of the DNA fragment. Librational motions are typically on the picosecond timescale and could entail interatomic distance fluctuations of up to 0.5 Å. These will not have serious effects on our structure determination. More difficult problems are posed by conformational fluctuations, which may occur on any timescale depending on the size of the energy barrier between the different conformers. Of course, with high barriers, conformational fluctuations are slow compared with chemical shift differences and separate resonances will be observed indicating the existence of different conformers. More deleterious are fast conformational fluctuations which average resonances.

If they are not recognized, internal motions can lead to systematically biased distances and distorted structures. Complicating the situation, the manner in which distances are averaged depends on the rate of exchange between conformers. The averaging in any case is not a simple geometric average of distances in the different conformers. Rather, when the internal motion is faster than the overall correlation time, e.g., with methyl rotation, the measured distance is subject to $\langle r^{-3} \rangle$ averaging, i.e., the apparent distance between a nucleus i and the set of motionally averaged nuclei j (e.g., the methyl protons) is generally slightly weighted toward the shorter of the distances if the internal motion is not isotropic,⁸ but the apparent distance is identically equal to the distance between nucleus i and the geometric mean position of nuclei j that are undergoing isotropic jumps.⁵² There is some evidence to suggest that sugar repuckering motions may occur in this time range and would thus be subject to $\langle r^{-3} \rangle$ averaging. However, if jumps between the individual conformers are slow compared with the reciprocal of the overall correlation time but fast compared with the relaxation time, the apparent distance is subject to $\langle r^{-6} \rangle$ averaging over individual proton positions; so, the apparent distance may be strongly distorted from the geometric average position. The occurrence of this situation might be expected for aromatic ring flips and maybe some methylene motions in proteins, but there is no evidence to date for motions in this time regime for DNA oligomers. As already noted, we have incorporated some motional information into our structure approach, such that the distortion of the *time-averaged* structure should be minimized. MARDIGRAS already accounts for methyl rotation and averaging of protein aromatic ring and methylene protons for determination of both best fit distances and bounds. Other conformational fluctuations can be explicitly specified by use of an order parameter at present.

Torsion angle restraints and scalar coupling follow a Karplus relationship, so they too are not geometrically averaged by conformational fluctuations. Even with perfect data, with such nongeometric averaging, the individual distance and torsion angle restraints will be internally inconsistent. In addition, any particular structural restraint which is averaged by conformational jumps is likely to have an averaged value that is not physically, i.e. energetically, reasonable. Of course, in practice, we have a compromise of the experimental restraints with maintenance of reasonable energies in the classical potential energy terms. So, if we are studying a molecule that does have a solution structure and only limited

conformational fluctuations, we can obtain a reasonable time-averaged structure.

There have been few detailed relaxation studies of DNA oligomers. However, with the advent of isotopic labeling (laborious as it is for DNA), from relaxation studies we can expect more information about the spectral densities associated with molecular motions in the near future. Relaxation data are well-suited to inform us about frequencies of motions and are modestly adapted to inform us about amplitudes of motions. However, they do not reveal the exact type of motion. We have been trying to develop a framework in which we can examine structure and relaxation data in a molecular context.

In spite of the increased accuracy of interproton distances afforded by MARDIGRAS analysis, we find certain discrepancies in distances, which can most readily be ascribed to limited conformational flexibility (internal motions). For example, for the octamer d(GTATAATG) · d(CATATTAC), the final structure resulting from rMD manifested some nonplanarity of some bases. This did contribute to an improvement in apparent agreement with the experimental data.⁴⁸ (Note that rMD does permit some distortion of bond lengths, bond angles, and torsion angles, with the energetic price paid in the classical potential energy terms compensated by a lowering of the experimental restraint violation energy. In contrast, the rMC method we employ dictates idealized base geometries.) Perhaps the most distorted base is A5. The experimental restraints, H-8A5–H-8A6 (2.69–2.99 Å) and H-2A5–H-2A6 (3.16–3.39 Å), cannot be satisfied simultaneously by any single conformation. As noted already, the rMC structures calculated for the octamer are essentially the same as the rMD structures (<0.5 Å RMSD). In rMC structures with idealized base geometries, the above two distances are 3.61–3.64 and 3.98–3.99 Å, respectively; but they are reduced to 3.52 and 3.75 Å in the final rMD structure. The latter values result from compromise between repulsive van der Waals forces and pseudoenergy forces from experimental restraints causing some distortion of A5.

We had previously found from $T_{1\rho}$ measurements that H-2A5 is involved in some dynamic process.⁵³ If there are some conformational fluctuations in this region causing changes in the relative orientations of the A5 and A6 bases, as illustrated in Figure 4, the H-8A5–H-8A6 and H-2A5–H-2A6 distances would fluctuate leading to an average value being determined. With averaging due to conformational fluctuations, the distance determined will likely be shorter than the geometric mean (see above). So measured distances for both H-8A5–H-8A6 and H-2A5–H-2A6 could be too short to be mutually consistent.

The H-6/H-8–H-2'/H-2'' and H-6/H-8–H-3' intraresidue distances are often internally inconsistent. The 2D NOE

Figure 4 Schematic of bases A5 and A6 of the base pair step AZ5-A6:T11-T12 of d(GTATAATG) · d(CATATTAC), exaggerating the effect of conformational flexibility on the H-8A5–H-8A6 and H-2A5–H-2A6 distances, which are shown by broken lines

intensities corresponding to H-6/H-8–H-2'/H-2'' distances are usually satisfied by all refined structures. Significant H-6/H-8–H-2'/H-2'' interactions imply that the deoxyribose conformation spends a large part of the time in an S-type conformation, i.e., with pseudorotation angle P_S in the range 120–210°. However, H-6/H-8–H-3' intrarésidue distances are typically slightly larger in refined rMD and rMC structures than would be implied by experimental cross peak intensities. This apparent inconsistency may be due to repuckering motions in the sugar ring. Such a repuckering is implied by our experimental scalar coupling data, where it is rarely possible to interpret the results in terms of a single sugar conformer (see above).

Since conformational fluctuations may influence the value of distance restraints extracted from 2D NOE spectra, an alternative distance penalty function has been proposed for use with restrained MD calculations.⁴⁶ The distance between any two protons and the associated penalty function is monitored as a running average with exponential weighting to emphasize more recent steps during an rMD simulation. This permits a broader search of conformational space in an rMD simulation,

as the calculation does not demand that the measured value of the distance be satisfied exactly at every single step of the simulation. A theoretical study suggested that this may be a valuable approach.⁵⁴ We have explored the use of MD with weighted time-averaged restraints (MD-tar) and found it can resolve some of the dynamics-related shortcomings of rMD and provide insight into the mechanics of DNA molecular motion.^{42,43} For d(GTATAATG) · d(CATATTAC), it was found that MD-tar, using only experimental distance restraints, generates an ensemble of structures that, as an ensemble, fit both the experimental 2D NOE data and the scalar coupling data better than the best structure obtained via traditional rMD methods.

With an ensemble of structures resulting from such an analysis, it is most appropriate to examine the structural parameters of the ensemble as a distribution of values. While we have calculated a large number of backbone torsion angles and helical parameters for the ensemble of 400 structures, only a representative three pseudorotation angle distributions are displayed in Figure 5. For A13, the distribution is similar to that of rMD, i.e., there is mostly only a single S conformer. For T14, a significant minor N conformer is also apparent in

Figure 5 Distribution of deoxyribose pseudorotation angles for three representative nucleotides in d(GTATAATG) · d(CATATTAC). Each distribution is composed of 400 values, calculated for the ensemble of 400 structures chosen every 0.25 ps during the last 100 ps of an MD-tar simulation: standard rMD with explicit solvent (---), MD-tar in vacuo (—), and MD-tar with explicit solvent (—)

Figure 6 The final refined structure of d(AGCTTGCCTTGAG) · d(CTCAAGGCAAGCT) obtained from rMD calculations

the MD-tar distribution, which is unlike the single S conformer resulting from standard rMD refinement. This is in accord with the two-state deoxyribose repuckering model often used to explain the scalar coupling constant data (see section 2.2), i.e., a major conformer nearly C-2'-endo and a minor conformer nearly C-3'-endo. However, the sugar rings of some residues manifest a distribution similar to that of A6, in which a minor S conformer, approximately O-4'-endo, is evident. In all the standard rMD refinements we have carried out, only a single conformer is obtained. As noted already, this is in conflict with our scalar coupling data, which indicate that in most residues at least one minor conformer must also exist. Clearly, the MD-tar results are in better agreement with these experimental results. We also found that the *R* factor calculated for the ensemble was in better accord with our experimental 2D NOE results than any single structure we had determined using rMD.

It was noted above that the H-8A5–H-8A6 and H-2A5–H-2A6 distances and the H-6/H-8–H-2'/H-2'' and H-6/H-8–H-3' intraresidue distances are inconsistent. Both sets of distances were better satisfied on a time-average basis in MD-tar simulations of the octamer due to repuckering of the sugar rings.

5 CONCLUSIONS

In summary, it is now possible to determine the time-averaged structure of a DNA duplex with fairly high precision and apparent accuracy, and it is possible to assess the quality of the structure. To do so, however, requires a large

number of accurate structural restraints well distributed in the molecule (especially distances) and a careful refinement of the structure using those restraints. Soon it may be possible to learn of some generalities in sequence-dependent structural features. Even with the few DNA duplexes for which we have determined high-precision structures, it is possible to discern a few tentative generalities. For example, the average helical twist in the structures of the three DNA duplexes mentioned in this article is 34.6°, in remarkable agreement with independent solution state data on DNA, and the value for DNA in crystals is 36°. The duplex d(AGCTTGCCTTGAG) · d(CTCAAGGCAAGCT), whose structure is shown in Figure 6, has two CTTG moieties and [d(GATGCAAATG) · d(CTACGTTTAC)] has one TG step. At all three TG steps, local structural variations work together to create bending into the major groove of the duplex. Although there are a few other suggestive structural generalities, more structural information is required.

Although we can now obtain good time-averaged structures, we are clearly at a stage when it is time to examine the dynamic aspects of structure. Conformational averaging, of course, complicates any determination of NMR-derived solution structures. However, the sensitivity of NMR to dynamic processes is ultimately an advantage rather than a shortcoming, because it can be used to study the conformational flexibility of DNA.

1 INTRODUCTION

Contemporary evaluation of the mounds of experimental data and theoretical work on the subject of nucleic acid structure, stability, recognition, and function concludes, not surprisingly, that stacking and pairing interactions of constituent nitrogenous bases constitute the greatest influence. Hence, issues such as polymorphism, curvature, and deformation at the polymer level may be best addressed via consideration of base composition and sequence. It is the steric, van der Waals, and electrostatic interactions of these units that primarily determine polymer properties.^{1,2}

More than three decades ago, with far less information and experience, similar conclusions were drawn by many working on nucleic acid structure, particularly dwelling upon helix-coil transformations wrought by heat and organic solvents.³⁻⁷ Studies on the tendencies of the bases and corresponding nucleosides to associate in aqueous media⁸⁻¹⁰ led to the postulate that these nucleic acid constituents mingled primarily via vertical stacking interactions of the bases rather than by hydrogen bonding mechanisms.

It is the intent of the present contribution to describe how proton NMR studies on these nucleic acid units definitively demonstrate vertical stacking combinations involving the bases themselves, and within higher ordered structures. Whereas these modes of association predominate in aqueous media, hydrogen-bonding-type interactions are shown by NMR to occur in denaturing solvents which prevent stacking and coincidentally denature nucleic acid helices, again demonstrating the importance of stacking in the structure and stability of these biopolymers.

Although we will trace the thread of import involving base interactions among higher ordered species, contributions by Hilbers, James, Cowburn, etc., are more focused upon aspects of structure, conformation, and dynamics at these levels of complexity (see *Nucleic Acids: Spectra, Structures, and Dynamics*; *Nucleic Acid Structures in Solution: Sequence Dependence*, and *Nucleic Acids: Chemical Shifts*, respectively).

2 SELF-ASSOCIATION OF BASES

2.1 Stacking Interactions

The suggestion that the mode of association for nucleic acid bases was different from the known hydrogen bonding motif of compounds such as urea was based upon their considerably disparate osmotic properties⁸⁻¹⁰ and influences upon lowering the thermal denaturation transition temperature, T_m , of DNA.¹¹ Inasmuch as purine and its 6-methyl derivative had association constants of 2.1 and 6.7 m and corresponding standard free energies -8.8 and -4686.1 J, the values for urea were 0.04 m and $+4979$ J. Moreover, urea was only 10% as efficient in lowering T_m for the thermal denaturation of DNA as purine. Consequently, in the light of the sensitivity of chemical shifts to shielding environments, ^1H NMR measurements of purine and 6-methylpurine versus concentration in water were conducted, and attempts made to elucidate the nature of their interactions.¹²

Presented in Figures 1 and 2 are the chemical shifts of nonexchangeable purine and 6-methylpurine protons in aqueous solution over the concentration range 0.05–1.0 m . Despite the somewhat primitive techniques available 30 years ago, namely, resonance frequency determined via superposition of audio sidebands from suitable references (in this case external chloroform and acetonitrile for aromatic and methyl protons, respectively), these proton peak positions, corrected for bulk susceptibility, are estimated to be accurate to ± 1 Hz at 56.4 MHz (1.33 T). The magnitudes of these concentration-induced low-frequency changes over the range 0.0 (extrapolated) to 1.0 m vary from about 0.5 ppm for H-8 of both bases to 0.6–0.8 ppm for protons on the pyrimidine rings, with larger effects seen for 6-methylpurine. The greater shift changes for the latter are consistent with the greater association tendencies measured by vapor pressure osmometry. Movement of the resonance position to lower frequency with increasing concentration is a consequence of diamagnetic ring current moments exerting shielding upon protons of neighboring associating bases arrayed in partial overlapping stacks

Figure 1 Concentration dependence of the ^1H chemical shifts for purine in aqueous solution at 25°C (corrected for bulk susceptibility); shifts measured from external chloroform reference: (o) experimental values; (x) calculated values from overall average model

Figure 2 Concentration dependence of the ^1H chemical shifts for 6-methylpurine in aqueous solution at 25°C (corrected for bulk susceptibility): (○) experimental values for H-2, H-8 proton shifts measured from external chloroform reference (left-hand coordinates); (▲) experimental values for methyl protons, shifts measured from external acetonitrile reference (right-hand coordinates); (×) calculated values from overall average model

(Figure 3). This interpretation is solidified via computation of expected shifts (xs in Figures 1 and 2) based upon the osmotic data and consideration of noticeable contributions from dimer and higher ordered arrays in fast ‘making and breaking’ exchange with monomer bases.¹³

The fact that attachment of an apolar methyl group increased the association, whereas increased temperature, solvents such as dimethyl sulfoxide (DMSO) and dimethylformamide, and generation of positive charges on the purine ring all obliterated the shift changes, led one to conclude at the time that the bases are complexing via some general descriptor such as ‘hydrophobic’ forces. Nowadays, in the light of more refined theoretical approaches,¹ it may be appreciated that

Figure 3 (a) Ring current-induced diamagnetic moment in aromatic ring system. (b) Total overlap and inplane interactional models with indication of positive reinforcement of peripheral-induced paramagnetic moments, thus shifts to higher frequency with such arrangements. (c) Partial vertical overlapping arrangement illustrating diamagnetic effects of one ring upon protons of neighboring ring, thus shifts to lower frequency

electrostatic interactions between stacking heteroaromatic bases involve fixed partial atomic charges and asymmetric σ and π electron distributions, as well as van der Waals steric considerations. Hydrophobic effects, e.g., the clustering of apolar solutes such as these bases, whilst maximizing solvent–water intermolecular hydrogen bonding networks are indeed also important, but are in balance with the aforementioned electrostatic attractive forces. For instance, whereas partial base overlap tends to maximize σ – π attraction (and this orientation is consistent with the concentration-induced upfield proton shifts), hydrophobic considerations would tend to drive the bases into complete overlap.

2.2 Base–Base Stacking Interactions in Nucleosides and Nucleotides

Further insight into the specific characteristics of the interactions of nucleic acid bases in more sophisticated structures was garnered via ^1H NMR studies of purine associating with pyrimidine nucleosides,¹⁴ purine nucleoside associations,¹⁰ and the interactions of mononucleotides with one another.^{13,15,16} The distillation of these studies revealed that the primary site(s) for the interactions in these systems were the bases. For instance, the diamagnetic effects accruing to purine base ring currents fell off with distance from the base as one traversed the carbohydrate moieties from the site of aglycone attachment to the exocyclic 5'-protons. Moreover, the greatest concentration-dependent upfield shifts were noted for the more highly base-methylated purine nucleotides. Finally, it was noted that the coulombic repulsion of the anionic phosphates diminished the concentration-dependent diamagnetic behavior in the mononucleotides.

2.3 Base–Base Stacking in Oligonucleotides

Although intimate discussion of structure and conformation in oligonucleotides and polymers is beyond the scope of this communication, it is instructive to highlight the influence of base stacking in some selected species containing sugar–phosphate backbones. Adenyl(3'–5')-adenosine (ApA) has been studied by a number of workers.^{17–22} The upshot of all these NMR investigations is that the adenine–adenine intramolecular base–base stacking in aqueous media is very strong, persisting even at 90°C ,^{19,20} but is obliterated in denaturing DMSO milieu. As a consequence of this strong propensity toward maintenance of base–base overlap, ribose ring puckering shifts to 3'-endo from the 2'-endo form favored in the mononucleotides, the glycosidic torsion angle moves toward zero degrees (more stringent *anti* conformation), and there is less flexibility in rotational conformers at other sites along the sugar–phosphate backbone.²²

Proton NMR studies of various diribonucleoside monophosphates with all combinations of purine and pyrimidine bases^{21,23,24} have revealed sequence-dependent base-stacking interactions and backbone conformations. While details of these molecular properties may be found elsewhere in this Encyclopedia, it is worth noting that if one uses backbone torsional angle criteria as a means of judging the extent of base–base interaction, one can derive the relative strengths of these associations as pyrimidine (pyr)–purine (pu) < pyr–pyr

$< \text{pu-pu} < \text{pu-pyr}$.^{23,24} However, using diamagnetic ring current induced 'dimerization' chemical shift changes,²¹ one would order the ascending strengths of base interactions as $\text{pyr-pyr} < \text{pyr-pu} < \text{pu-pu} < \text{pu-pyr}$. The latter ranking is based upon the predominant *anti,anti* glycosidic conformation plus right-handed helical sense of the backbone.

2.4 Base Stacking as the Predominant Influence in Nucleic Acid Structure

There appear to be two current views on the relative importance of base stacking versus sugar-phosphate backbone flexibility and conformational preference in the overall three-dimensional structures of oligonucleotides and nucleic acids. (1) Maximizing the strong base-base stacking interactions drives the conformational properties of the backbone. (2) The reverse, i.e., base stacking, happens as a consequence of the backbones being in one or more suitable arrangements. Based upon the foregoing discussions of monomer association tendencies, involving strong electrostatic, dispersion, and van der Waals forces accompanying base-base contact plus the need to minimize disruption of solvent-water structure, one might opt for choice (1). As a matter of fact, current thought emphasizes the preeminent influence of base stacking and the nature of base-paired dimer 'steps' in determination of nucleic acid preferred overall structure.^{1,2} It is the contention in these two cited works that the 'B' to 'A' transition as well as the existence of the ubiquitous Z-DNA are all dependent upon the sequence of base-stacked pairs, which may interact in two or more 'stable' arrangements, thus providing energy wells for the overall conformational characteristics.

2.5 Thermodynamics of Base Stacking

Thermodynamic considerations reinforce the NMR data demonstrating the strong base stacking association. For instance, Tinoco et al.²⁵ summarize the results of several optical studies giving the enthalpy of adenine-adenine stacking in ApA as -20 to $-41.8 \text{ kJ mol}^{-1}$. In fact, from the temperature dependence of the NMR spectrum of the cyclophosphate derivative of ApA, $\text{ApA} >$, which yielded equilibrium constants for the exchange between stacked and unstacked forms, Hruska and Danyluk¹⁷ derive a base stacking enthalpy of $-34.3 \text{ kJ mol}^{-1}$. These findings point out the considerable stabilizing influence of base stacking in nucleic acid structures.

2.6 What About Base Pairing?

It is universally known that recognition and genetic information transfer in nucleic acid interactions involves specific base pairing. The demonstration of these specific hydrogen bonding interactions involving imino and amino protons using NMR in aqueous media, as described elsewhere in this Encyclopedia, is also well known. It is difficult to observe these specific base pairing hydrogen bonding interactions for aqueous solutions of oligonucleotides smaller than pentamers (other than at high concentrations and/or low temperatures) because the negative enthalpy change for such pairing is probably no more than some hundred J

mol^{-1} , thus lifetimes for the hydrogen bonded states are short and exchange with solvent is rapid. Moreover, when one does observe base pairing between small oligomers at high concentrations and low temperatures, trimeric species form.²⁵

2.7 Monomer Base Pairing in Organic Solvents

At approximately the same point in history that NMR techniques were being used to demonstrate base stacking in aqueous solution, they were being similarly employed to illustrate base pairing in aprotic solvents such as chloroform and DMSO, solvents in which, particularly the latter, stacking interactions are nil and nucleic acid structure denatured. Katz and Penman,²⁶ and Shoup et al.²⁷ showed via large specific downfield shifts at 60 MHz (1.41 T) that complementary Watson-Crick (WC) hydrogen bonded complexes formed between guanine and cytosine derivatives in DMSO. In this strong hydrogen bond accepting solvent, acidic imino protons of guanine shifted 1–2 ppm to higher frequency and guanine and cytosine amino proton shifts shifted 0.5–1 ppm, depending upon the mole ratios of donor and acceptor molecules. These shifts were much larger than those found for self-association of the interactants and no low-frequency shifts for carbon-bound protons with concentration increase were noted, reinforcing the statements made earlier that DMSO obliterates base stacking.

Adenine and thymine (or uracil) hydrogen bonding interactions were quite weak in DMSO, but in chloroform, offering less competition for hydrogen bond acceptance, Katz and Penman found large high-frequency shifts in mixtures of 9-ethyladenine and 1-cyclohexyluracil, the magnitude again reflecting the relative acidities, e.g., about 3 ppm for uracil N-3 imino and 0.7 ppm for adenine amino protons. No non-WC pairs were in evidence. These results in chloroform complemented the infrared studies of Hamlin et al.,²⁸ and Pitha et al.,²⁹ who showed that the WC pairing led to specific hydrogen bond stretching bands.

In a higher field (2.35 T) study with chemical shifts accurate to $\pm 0.1 \text{ Hz}$, Newmark and Cantor³⁰ demonstrated that guanosine does form hydrogen bonded dimers in DMSO, most likely similar to the arrangements found in the gel state in aqueous solution [Figure 4(a)]. Shifts to higher frequency were of the order of 0.08 to 0.020 ppm with a formation constant of 0.18 l mol^{-1} at 32°C . As Newmark and Cantor note, dimers form in DMSO, but large aggregates, e.g. gels, form in water,³⁰ implying large base stacking free energies in the aqueous environment.

This guanosine self-interaction pales in comparison with the guanosine-cytidine base pairing [Figure 4(b)] as noted above, where one finds as did Katz and Penman, that guanosine amino and imino protons shift to higher frequency by 0.5 and 1.5 ppm, respectively, while cytidine amino groups move 0.4 ppm to higher frequency. Newmark and Cantor calculate a formation constant of 3.71 mol^{-1} and an enthalpy change of -25 kJ mol^{-1} for this complementary WC pairing interaction (from van't Hoff plots of the logarithm of the dimer formation constant vs. reciprocal temperature).

3 SUMMARY

Three decades ago ^1H NMR investigations revealed that simple nitrogenous bases self-associated in aqueous media

Figure 4 (a) Hydrogen bonding scheme for guanosine dimer formation in DMSO. (b) Watson-Crick complementary hydrogen bonding between guanosine and cytosine in DMSO

via vertical stacking with partial ring overlap. These strong solute-solute interactions, on the order of -20 to -41.8 kJ mol $^{-1}$, are believed to have electrostatic and dispersive origins by virtue of asymmetric π and σ electron distributions as well as hydrophobic contributions from solvent water. Evidence from ^1H NMR of base stacking persists with higher structural order, in nucleosides and nucleotides, oligonucleotides, and nucleic acid polymers. Stacking of bases is thus a major contributor to nucleic acid structural integrity and in fact may govern overall polynucleotide configurational states.

Complementary WC base pairing in aprotic solvents was also observed by ^1H NMR over 30 years ago. These interactions, now readily monitored directly at high field, although contributing less to structure than stacking, are the crux of information transfer.

1 INTRODUCTION

It would have been difficult to imagine in the early development of NMR that ^{31}P NMR, with such relatively low sensitivity, could ever be used for understanding the detailed structure and dynamics of macromolecules such as deoxyribonucleic acid (DNA). With the tremendous increase in sensitivity in modern FT NMR spectrometers, biological applications of ^{31}P NMR spectroscopy grew dramatically during the 1970s and 1980s and has continued to grow into the 1990s, as briefly described in Volume 1 of this series.¹ A number of monographs^{2–5} entirely devoted to ^{31}P NMR, covering theory and applications to organophosphorus, and biological and medical aspects of the field have been published. A number of review articles on ^{31}P NMR of nucleic acids and nucleic acid complexes^{6–11} have also appeared.

Until recently ^{31}P NMR studies of nucleic acids were restricted to partial identification of signals for polymeric nucleic acids and oligodeoxyribonucleotide sequences of less than six base pairs in length.² However, synthetic schemes have now been developed where defined deoxy- (and more recently ribo-, and backbone modified-) oligonucleotides can be routinely produced in multimilligram quantities. The concomitant development of sequence-specific two-dimensional (2D) $^1\text{H}/^1\text{H}$ and $^1\text{H}/^{31}\text{P}$ NMR assignment methodologies^{12–21} has made the assignment of the ^{31}P NMR spectrum of modest size oligonucleotides (8–14 base pairs) possible.

Traditionally the phosphate ester moiety is often overlooked and viewed as a passive element of nucleic acid structure. Base pairing and other nucleic acid base-oriented structural features have been assumed to control nucleic acid structure and conformation. More recently (and as discussed in this chapter) we have begun to appreciate the important role played by the phosphate ester in defining the structure and dynamics of nucleic acids as well as nucleic acid–drug or –protein complexes.

Phosphorus-31 chemical shifts and ^1H - ^{31}P coupling constants of nucleic acids can provide valuable information on the conformation of the phosphodiester backbone.^{11,22–25} It

is now widely appreciated that significant local conformational heterogeneity exists in the global as well as the local structures of nucleic acids.^{26–29} The internucleotide linkage is defined by six torsional angles from one phosphate atom to the next along the DNA backbone. Theoretical studies have shown that the conformation of two of the six torsional angles (α : $\text{O}-3'-\text{P}-\text{O}-5'-\text{C}-5'$ and ζ : $\text{C}-3'-\text{O}-3'-\text{P}-\text{O}-5'$) appear to be most important in determining ^{31}P chemical shifts.^{22,25,30} Molecular dynamics calculations,³¹ X-ray diffraction,³² and 2D NMR^{33–35} spectroscopy have also shown that the phosphate ester conformation is the most variable and dynamic part of nucleic acid structure.

2 ASSIGNMENT OF THE ^{31}P NMR SPECTRA OF OLIGONUCLEOTIDES

Prior to the development of multidimensional NMR methods for the sequence-specific assignment of the ^{31}P spectra of nucleic acids, ^{17}O -labeling provided the only unambiguous assignment methodology.^{19,36–40} However, the site-specific labeling of the monesterified phosphoryl oxygens of the backbone with ^{17}O or $^{17}\text{O}/^{18}\text{O}$ suffers by being expensive and time consuming. Multidimensional ^{31}P - ^1H NMR spectroscopy^{20,39,41,42} has provided a convenient, inexpensive alternative for the assignment of ^{31}P chemical shifts in moderately sized oligonucleotides. Conventional 2D ^{31}P - ^1H heteronuclear correlation (HETCOR) NMR spectroscopy has been applied with limited success to short oligonucleotides.^{20,38} For oligonucleotides longer than 4 or 5 nucleotide residues the simple heteronuclear correlation measurements suffer from poor sensitivity as well as poor resolution in both the ^1H and ^{31}P dimensions. The poor sensitivity is largely due to the fact that the ^1H - ^{31}P scalar coupling constants are about the same size or smaller than the ^1H - ^1H coupling constants. Sensitivity is substantially improved by using a heteronuclear version of the 'constant time' coherence transfer technique, referred to as COLOC (CORrelation spectroscopy via LONG range Coupling), originally proposed for ^{13}C - ^1H correlations,⁴³ and implemented in a Pure Absorption phase Constant time pulse sequence (PAC) to emphasize ^1H - ^{31}P correlations in oligonucleotides.³⁹

Besides the ^{31}P - ^1H long-range constant time HETCOR,^{39,44} 2D heteronuclear J cross-polarization heteroTOCSY,^{45–49} 2D heteronuclear TOCSY-NOESY,⁵⁰ 2D TOCSY/ ^1H - ^{31}P INEPT,^{45,51} and other indirect detection (^1H detection) HETCOR experiments,^{42,52,53} have been successfully used to assign ^{31}P signals in 6–14 base pair (bp) duplex DNA and ribonucleic acid (RNA). A very nice 3D heteroTOCSY-NOESY experiment⁵⁴ has recently been developed that promises increased spectral dispersion by adding a third frequency dimension. This may prove to be extremely valuable for ribooligonucleotides where very little ^1H spectral dispersion in the sugar protons is unfortunately observed.⁵⁰

3 ^1H - ^{31}P AND ^{13}C - ^{31}P COUPLING CONSTANTS

In order to understand the structural factors contributing to the variation in ^{31}P chemical shifts of nucleic acids, it has proven to be critical to be able to measure the

backbone torsional angles. Fortunately the three-bond $J(^{31}\text{P},\text{H}-3')$ coupling constants in oligonucleotide duplexes can often be readily determined from the selective 2D J -resolved spectrum.⁵⁵ In nearly all duplex oligonucleotides a very interesting pattern of monotonically decreasing coupling constants for the signals to higher field is observed^{30,55–59} and strongly supports a correlation between ^{31}P chemical shifts and $J(^{31}\text{P},\text{H}-3')$ coupling constants.

The observed three-bond coupling constants can be analyzed with a proton–phosphorus Karplus relationship to measure the $\text{H}-3'-\text{C}-3'-\text{O}-\text{P}$ torsional angle θ from which the $\text{C}-4'-\text{C}-3'-\text{O}-\text{P}$ torsional angle ϵ ($= -\theta - 120^\circ$) may be calculated.⁶⁰ As shown by Dickerson and Drew^{26,27} there is a strong correlation ($R = -0.92$) between torsional angles $\text{C}-4'-\text{C}-3'-\text{O}-3'-\text{P}$ (ϵ) and $\text{C}-3'-\text{O}-3'-\text{P}-\text{O}-5'$ (ζ) in the crystal structures of various duplexes. Thus both torsional angles ϵ and ζ can often be calculated from the measured $\text{P}-\text{H}-3'$ coupling constant.

A plot of observed ^{31}P chemical shifts and $J(^{31}\text{P},\text{H}-3')$ coupling constants is shown Figure 1.⁵⁷ In addition the Karplus relationship is plotted.⁶⁰ The Karplus relationship provides for four different torsional angle solutions for each value of the same coupling constant. Although all four values are shown in Figure 1, the limb that includes ϵ values between 0 and -270° is sterically inaccessible in nucleic acids.²⁸ Generally it is assumed that the coupling constants, which can vary only between 1 and 11 Hz, all correspond to ϵ torsional angles on a single limb nearest the crystallographically observed average for nucleic acids²⁸ ($\epsilon = -169 \pm 25^\circ$). This need not always be true, especially since phosphate ester conformations corresponding to either of the other two solutions are observed crystallographically.²⁸ However, as shown in Figure 1, nearly all of the phosphates for normal Watson–Crick duplexes fall along only a single limb of the Karplus curve. Exceptions include several phosphates adjacent

to some guanine–adenine (GA) mismatch duplexes.^{61,62} In addition, it is quite interesting that the measured ^{31}P chemical shifts and coupling constants for the two phosphates at the site of a tetramer duplex actinomycin D–drug complex do not fit on the main limb of the Karplus curve, although the values do fit nicely on the other two solutions of the curve (Figure 1). Indeed crystal structures²⁸ of related intercalator duplex complexes confirm that the phosphates are often constrained to conformations that best correspond to the other solutions. These intercalator drug–duplex complexes quite generally show large high-frequency (downfield) shifts of the ^{31}P signals.^{23,63,64}

It is important to emphasize that ^{31}P chemical shifts are dependent on factors other than torsional angles alone.^{22,65–69} Under normal physiological solution conditions, the intrinsic torsional effects appear largely to dominate ^{31}P chemical shifts of phosphate esters. Thus, for ‘normal’ B-DNA geometries, there is an excellent correlation (-0.81 ; Figure 1) between the phosphate resonances and the observed torsional angle, whereas phosphates that are greatly distorted in their geometry must be more carefully analyzed.³⁰ Importantly, knowledge of both the ^{31}P chemical shift and the $J(^{31}\text{P},\text{H}-3')$ coupling constant can be very helpful in the proper interpretation of phosphate ester conformation.

Analysis of natural abundance 2D $^{13}\text{C}-^1\text{H}$ HMQC and HSQC spectra also allows the measurement of additional $^{31}\text{P}-^1\text{H}$ and $^{31}\text{P}-^{13}\text{C}$ coupling constants.⁷⁰ This should in the future provide further verification of the conformational dependence on ^{31}P chemical shifts.

Roongta et al.⁵⁷ have analyzed the variation in the ^{31}P chemical shifts and $J(^{31}\text{P},\text{H}-3')$ values (Figure 1) in terms of fractional populations of the two thermodynamically stable, B-DNA backbone conformational states, B_I and B_II . In the normally favored B_I state $\epsilon = t$ (*trans*, 180°) and $\zeta = g^-$ (*gauche*, -60°), whereas in the B_II state $\epsilon = g^-$ and

Figure 1 Plot of ^{31}P chemical shifts for the oligonucleotide sequences previously studied in our laboratory^{30,57,107} (○) and the actinomycin-D-bound d(CGCG)₂ tetramer complex¹⁰⁸ (□) with their measured $J(^{31}\text{P},\text{H}-3')$ coupling constants (the ○ data points correspond to phosphates in a tandem GA-mismatch decamer duplex,⁶² which shows unusual, slowly exchanging signals). Also shown are the theoretical ϵ and ζ torsional angles (solid curve) as a function of coupling constant derived from the Karplus relationship (ϵ) and the relationship $\zeta = -317 - 1.23\epsilon$. Phosphorus-31 chemical shifts are reported relative to trimethyl phosphate. Reproduced by permission of the American Chemical Society from Nikonowicz and Gorenstein⁶²

$\zeta = t$. Actually in the crystal structure data, the average ϵ torsional angle value for the B_I state is -190° and for the B_{II} state is -105° .^{26,27} These ϵ values approximate the maximum possible range of $J(^{31}\text{P}, \text{H}-3')$ coupling constants [for $\epsilon = -105^\circ$, $J(^{31}\text{P}, \text{H}-3') = 10.0 \text{ Hz}$ and for $\epsilon = -190^\circ$, $J(^{31}\text{P}, \text{H}-3') = 1.3 \text{ Hz}$]. In addition in this torsional angle range, the Karplus curve is nearly a single-valued function (actually it is only single valued in the range of $\epsilon \approx -200$ to -120° ; between -105 and -120° the coupling constant is in the range of 10.0 – 10.8 Hz). The measured coupling constant then represents the weighted average of the coupling constants in the two states. The ^{31}P chemical shift and $J(^{31}\text{P}, \text{H}-3')$ coupling constant of a phosphate in a purely B_I conformational state is estimated to be about -4.6 ppm and 1.3 Hz , respectively. Similarly the ^{31}P chemical shift and $J(^{31}\text{P}, \text{H}-3')$ coupling constants of a phosphate in a purely B_{II} conformational state should be about -3.0 ppm and 10 Hz , respectively. The ^{31}P chemical shift difference between the B_I and B_{II} conformational states is thus estimated to be 1.6 ppm . Earlier chemical shift calculations^{71–73} and later empirical studies indicated that a phosphate diester in a B_I conformation should have a ^{31}P chemical shift 1.5 ppm upfield from a phosphate diester in the B_{II} conformations.^{7,64} It is thus extremely gratifying that the experimentally observed results fully support the original hypothesis.

The dispersion in the ^{31}P chemical shifts of regular oligonucleotides is thus likely to be attributable to different ratios of populations of the B_I and B_{II} states for each phosphate in the sequence. Assuming that only the staggered rotamers define stable conformations, the phosphate is assumed to make rapid jumps between the two states. Alternatively the phosphate could be considered to be constrained to a single, intermediate P–O ester conformation. This latter explanation appears to be ruled out by restrained molecular dynamics simulations³¹ that clearly show that these intermediate conformational states are only transiently populated as the phosphate makes rapid jumps between the B_I and B_{II} states (see Section 5). Thus the measured coupling constant appears generally to reflect the populations of these two possible conformational states.

4 ^{31}P NMR OF POLYNUCLEIC ACIDS

Phosphorus-31 NMR may usefully be applied to the study of polynucleic acids as well.⁶ As described above, the range of ^{31}P chemical shifts for individual phosphates in duplex fragments is generally $<0.9 \text{ ppm}$. It is not surprising therefore that individually resolved signals are not observed for longer ($>100 \text{ bp}$) nucleic acid fragments, for which much broader lines are expected. In favorable circumstances, however, separate signals may be resolved.

Thus sonicated poly(A)-poly(U) ($U = \text{uridine}$) ^{31}P spectra show two equal intensity signals separated by about 0.4 ppm (-1.2 and -1.6 ppm relative to $85\% \text{ H}_3\text{PO}_4$).⁷⁴ Joseph and Bolton⁴⁰ showed by ^{17}O labeling of the phosphates that the two main ^{31}P signals are associated with phosphates in alternating conformations along the duplex poly(A)-poly(U) rather than the phosphates in the two different strands.

One of the earliest, most direct indications that ^{31}P chemical shifts were dependent on phosphate ester conformations comes from the study of poly d(GC) duplex ($C = \text{cytidine}$) and shorter oligomeric GC and related base duplexes. In high salt, the

^{31}P spectra of these alternating duplexes (including an RNA duplex) shows two signals of equal area with a chemical shift difference of 1.4 – 2.0 ppm .^{75–79} The crystal structures of this high-salt left-handed Z-DNA conformation show an alternation along the sugar phosphate backbone (α , ζ) of either B_I -like (g^+ , g^+ for CpG; $p = \text{phosphate}$) and B_{II} type (g^+ , t or g^- , t for GpC) phosphates.^{80–82} Skelenar and Bax⁸³ have nicely used the 2D heteronuclear indirect detection experiment to assign the downfield shifted signal to the B_{II} type of phosphates.

5 SEQUENCE-SPECIFIC VARIATION IN ^{31}P CHEMICAL SHIFTS AND COUPLING CONSTANTS OF DUPLEX OLIGONUCLEOTIDES

As pointed out by Ott and Eckstein⁸⁴ and Schroeder et al.,^{14,19} variations in local, sequence-specific, and induced environmental distortions in the duplex geometry appear to be responsible for the variations in ^{31}P chemical shifts. Earlier attempts in my laboratory and that of Eckstein utilized a set of simple ‘Calladine Rules’ to predict local helical structure. Thus Dickerson and co-workers⁸⁵ had shown that the helical distortions observed in the crystal structure of $d(\text{GCGCAATTGGC})_2$ ($d = \text{deoxy}$; $T = \text{thymine}$) could be quantitatively predicted through a series of simple ‘Calladine rule’ sum function relationships.⁸⁶ Based upon the ^{31}P assignments of over a dozen oligonucleotides, we were able to establish a modest correlation between ^{31}P chemical shifts and the helical twist sum function for a number of the oligonucleotides.^{14,19,30,87}

However, it is now clear that the failure to observe significant correlation between ^{31}P chemical shifts of all phosphates in duplex oligonucleotides and the sequence-specific local helical structural ‘rules’, as derived from X-ray crystal structures, simply reflects the failure of the rules themselves to predict accurately the solution state sequence-specific local, helical, structural variations.^{7,31,88–93} Further, recent NMR studies have suggested that the duplex conformation in solution may not be identical to the static picture provided by X-ray diffraction in the crystal state,^{42,94} as one might expect.

5.1 Origin of Sequence-Specific Variations

Analysis of the X-ray crystal structures^{26–28} and NOESY distance-refined structures⁹⁵ of B-form oligodeoxyribonucleotides has shown that torsional angles α , β and γ on the $5'$ -side of the sugar are largely constrained to values g^- (-60°), t (180°), g ($+60^\circ$), whereas significant variations are observed on the $3'$ -side of the deoxyribose phosphate backbone. The greatest variation in backbone torsional angles is observed for ζ (P–O–3'), followed by ϵ (C–3'–O–3'), and then δ (C–4'–C–3'). It is important to note that many of these torsional angle variations are correlated as in the B_I/B_{II} states.^{26–28,30}

It is largely this variation in δ , ϵ , and ζ that allows the sugar phosphate backbone to ‘stretch’ or ‘contract’ to allow for sequence-specific variations in the local base-pair geometry of B-DNA. Thus the possible basis for the correlation between base sequence and ^{31}P chemical shifts in both nucleic acids can be analyzed in terms of sugar phosphate

backbone distortions.³⁰ This backbone linkage provides a connection between ^{31}P spectral changes and variations in local helical parameters such as rise, twist, and roll. Indeed a correlation exists between the $J(^{31}\text{P}, \text{H}-3')$ coupling constant and calculated intersugar distances derived from the NOESY distance-restrained molecular dynamics (MD) refined structure for a decamer.³¹ Thus, a lengthening of the tether requires an increase in the population of the B_{II} conformation and shifts the ^{31}P signal to higher frequency.

5.2 Correlation of Local Helical Geometry with Backbone Conformation

X-ray, NMR, and computational methods now all agree that there are major backbone conformation changes introduced as a result of sequence-specific, local helical variations. Various molecular modeling studies^{30,96} have shown that B_{II} phosphates are associated with high values of helix twist³⁰ and large negative values of helix roll.^{58,96} High twist and low positive roll perturb the phosphate ester backbone and decrease base stacking interactions in TpA relative to ApT.^{58,97} Similar effects are noted for the Py-Pu (Py = pyrimidine, Pu = purine) sequence CpG vs. Pu-Py sequence GpC.^{58,97,98} When both B_{II} phosphates are opposite each other in a duplex step, as the phosphates turn toward the minor groove, they force the base pairs to be displaced into the major groove by up to 2 Å.⁹⁶ This results in some loss of stacking energy. With a large negative roll, the effect is to produce a kink toward the minor groove in the DNA at this juncture, producing a significant local bend in the duplex. Indeed in several instances of a GA mismatch, a very high twist value is found at a base step with either phosphates always in a B_{II} conformation⁹⁹ or phosphates predominantly in the B_{II} conformation.⁶²

High-frequency phosphate signals generally appear to be associated with Py-Pu base steps^{30,57,58,96,100} that have high helical twist. High twist produces an increase in the length of the sugar phosphate tether, also lowering the relative energy difference (and energy barrier?) between the two phosphate states. This produces a more flexible phosphate site in which transitions can occur more readily and in higher frequency, as appears to be observed in the MD simulations. CpG steps generally show high-frequency signals with large 3-bond coupling constants, whereas ApT steps show low-frequency signals with small 3-bond coupling constants.

5.3 Conformation and Dynamics of the Phosphate Ester Backbone

As described above ^{31}P chemical shifts and $^1\text{H}-^{31}\text{P}$ coupling constants clearly indicate sequence-specific variations in the backbone conformation. Unfortunately, $^1\text{H}/^1\text{H}$ 2D nuclear Overhauser effect spectra (NOESY) give no direct information on the phosphate ester conformation and NOESY distance-constrained structures have been suggested to be effectively disordered in this part of the structure.⁹⁵ The solution structural refinements of a d(CGCTTAAGCG)₂ decamer duplex, tandem GA mismatch decamer, and several tetradecamers^{101–103} by a hybrid relaxation matrix/NOESY distance-restrained MD methodology (MORASS)^{7,94,104–106} provided important

indicators that full analysis of DNA structure requires a complete picture of the internal dynamics.

The NMR restrained MD trajectory (time course) of the variations in the six backbone torsional angles, α – ζ of the internucleotide linkage in various duplexes, have indicated that most of these torsional angles show relatively small amplitude fluctuations about the average B-DNA values for the 45 picosecond restrained MD calculation. As noted above in B-DNA the ϵ and ζ torsional angles show the largest variability, and indeed calculations demonstrate that large amplitude fluctuations occur for these two torsional angles.^{26,27} These torsional angle changes reflect a transition from the low-energy B_{I} conformation to the higher energy B_{II} conformation. These transitions were short lived and relaxed back to the low-energy conformation. Other internucleotide phosphates show similar transitions, although the fraction of $\text{B}_{\text{I}}/\text{B}_{\text{II}}$ states varies for each phosphate. These calculations also provided strong support for the coupled ‘elbow’ conformational transition between the B_{I} and B_{II} conformations and the strong correlation between the ϵ and ζ torsion angles observed in the X-ray crystal structures of B-DNA.^{26,27}

As shown in Figure 2 the NOESY distance-restrained MD calculations for the tandem GA-mismatch d(CCAAGATTGG)₂ are able to reproduce the observed variation in the ϵ torsional angles for the decamer as calculated from the experimental $J(^{31}\text{P}, \text{H}-3')$ coupling constants.⁶² (The ϵ torsional angles also rather accurately parallel the variation in ^{31}P chemical shifts.) The ϵ torsional angles were calculated by averaging over 160 ps dynamics of the 2D NOESY restrained MD refinement. It is clear that a remarkably strong correlation exists between the pattern of the variation of the torsional angles derived from the restrained MD calculations and the experimentally measured coupling constants (the fit is poorer to an alternate conformation that is in slow chemical exchange; • in Figure 2). Similar correlations between the averaged torsional angles from restrained MD refinement of the d(CGCTTAA GCG)₂ base-paired B-DNA decamer have also been demonstrated.³¹

It is important to note that the ϵ torsional angles in Figure 2 derived from the restrained MD calculations represent time averages during which large amplitude fluctuations are

Figure 2 Plot of the ϵ torsion angle from the crystal structure (x) and final solution structure (□) vs. phosphate position along the 5′–3′ strand for duplex decamer d(CCAAGATTGG)₂. The experimental $J(^{31}\text{P}, \text{H}-3')$ coupling constant (○, ●) vs. phosphate position is also shown. The $J(^{31}\text{P}, \text{H}-3')$ coupling constant vs. sequence plot has been scaled to reflect the ϵ torsion angle variations. Reproduced by permission of the American Chemical Society from Nikonowicz and Gorenstein⁶²

observed on the picosecond timescale. The time course of the restrained MD calculated fluctuations about the six sugar phosphate torsional angles in the GA-mismatch decamer show relatively small amplitude fluctuations about the average B-DNA values except for the ϵ and ζ torsional angles. These torsional angle changes again generally reflect a transition from the low-energy B_I conformation to the higher energy B_{II} conformation.

Figure 2 also demonstrates that the variation in the backbone conformation in the crystal state follows the same pattern of variation in the measured coupling constants and the averaged torsional angles derived from the restrained MD refinement. In the crystal state, most of the phosphates appear frozen in either pure B_I or pure B_{II} conformations. At any single snapshot of the restrained MD calculations, some phosphates are also frozen in pure B_I or pure B_{II} conformations. However analysis of the ϵ torsional angle in any single snapshot during the MD trajectory leads to an incorrect value for the ϵ torsional angles as measured by the $J(^{31}\text{P},\text{H}-3')$ coupling constants. It is only the time average of the torsional angles that correctly describes the pattern of $J(^{31}\text{P},\text{H}-3')$ coupling constants. (In another tandem, GA-mismatch duplex conformational constraints on the backbone are sufficiently strong so as to keep two of the phosphates locked in a B_{II} state; and the ^{31}P chemical shifts of these phosphates are shifted to higher frequency as expected.⁹⁹) These results and those described in the previous section provide strong support for our hypothesis that *dynamic* variations in the backbone torsional angles are largely responsible for ^{31}P chemical shift variations in duplex oligonucleotides.

1 INTRODUCTION

NMR spectroscopy has come a long way since its inception. Initially used to study the (relaxation) properties of nuclear spins, the discovery of the chemical shift established it as one of the essential analytical techniques in chemical research laboratories. More recently it has developed into the most powerful technique for the determination of (bio)molecular structure in solution and has thereby made its way into the field of structural biology. This is one of the fascinating developments of this spectroscopy, never anticipated at the time of its conception.

In X-ray diffraction, traditionally used to determine the three-dimensional structure of biomacromolecules at atomic resolution, the wavelength of the electromagnetic radiation needed to obtain well-resolved diffraction patterns is of the order of the interatomic distances in the molecule, i.e. of the order of angstroms. The situation is quite different for NMR spectroscopy, where the wavelength is of the order of meters. Here, the required structural information has to be deduced from suitable spectral parameters, i.e. the intensity of the resonance lines, which corresponds to the number of nuclei in a particular chemical group, the splittings of the individual resonance lines from which torsion angles may be derived, and the relaxation properties leading to the nuclear Overhauser effect from which the short range distances ($<5 \text{ \AA}$) in the molecule can be calculated.

The complicated spectra of biomacromolecules with their strongly overlapping resonances do not lend themselves to easy abstraction of spectral parameters needed for structure determination, and ingenious methods have been devised to achieve this goal, revolutionizing the field of NMR. Although most of these developments have been initiated in protein studies, this is also reflected in present-day nucleic acid NMR. Part of the progress was connected with the possibility of performing heteronuclear NMR of uniformly ^{13}C - and ^{15}N -enriched proteins. Preparation of uniformly isotope-enriched ribonucleic acid (RNA) has now also come within reach and has led to a situation that, in principle, a complete

interpretation of the spectra of these molecules can be obtained.

Here we will outline the methods by which such an interpretation can be achieved and how the results are translated into structure. Subsequently, some hairpin structures and their loop folding will be discussed as examples. Aspects of internal mobility in nucleic acids are considered in the last part of this article.

2 NOMENCLATURE

A discussion of the spectral interpretation and structure determination of nucleic acids requires a definition of the parameters describing the geometry of the molecules, i.e. for our particular purpose an atom-numbering scheme and a definition of the torsion angles. The numbering scheme for the furanose ring and the five common bases in deoxyribonucleic acid (DNA) and RNA, as well as the definition of the sugar-phosphate backbone torsion angles, of the torsion angles of the sugar ring, and of the glycosidic torsion angle are presented in Figure 1 (see for their definition also Table 1). The values of the torsion angles are defined via the so-called Newman projections. Examples of such projections with the corresponding sign convention for the staggered conformations, *gauche*-minus (g^-), *gauche*-plus (g^+), and *trans* (t) are given in Figure 2. A more extensive treatment of this material can be found in Saenger.¹ The furanose ring is most conveniently described in terms of the phase angle of pseudorotation, P , and the puckering amplitude, Φ_m (see below).

3 STRUCTURAL PARAMETERS

A typical aspect of NMR spectroscopy is that only local or short range structural information can be obtained. Thus, distances derived from NOE measurements are generally $\leq 5 \text{ \AA}$ and only individual torsion angles can be derived from J couplings between protons, between protons and so-called heteronuclei (^{13}C , ^{15}N , ^{31}P), and between heteronuclei (^{13}C , ^{15}N ,

Table 1 Definition of Torsion Angles

	Atom sequence defining torsion angle
Sugar-phosphate backbone torsion angle	
α	O-3'-P-O-5'-C-5'
β	P-O-5'-C-5'-C-4'
γ	O-5'-C-5'-C-4'-C-3'
δ	C-5'-C-4'-C-3'-O-3'
ϵ	C-4'-C-3'-O-3'-P
ζ	C-3'-O-3'-P-O-5'
χ (Pyrimidine)	O-4'-C-1'-N-1-C-2
χ (Purine)	O-4'-C-1'-N-9-C-4
Endocyclic sugar torsion angle	
ν_0	C-4'-O-4'-C-1'-C-2'
ν_1	O-4'-C-1'-C-2'-C-3'
ν_2	C-1'-C-2'-C-3'-C-4'
ν_3	C-2'-C-3'-C-4'-O-4'
ν_4	C-3'-C-4'-O-4'-C-1'

Figure 1 Structures and standard atom numbering of the β -D-ribose and the five common bases (pyrimidines: C, T, and U; purines: G and A) in DNA and RNA according to the IUPAC/IUB guidelines (*Eur. J. Biochem.*, 1983, **131**, 9). Notice that the atoms in the sugar moieties are primed in contrast with the atoms in the bases. Note that the C, H numberings are only depicted as subscripts *within* the Figure, e.g. C₆ in Figure $\equiv$ C-6 in text. The numbering of the primed and double primed hydrogen atoms attached to C-5' is obtained by looking along the main chain: proceeding in the counterclockwise direction the atoms attached to C-5' are C-4', H-5' and H-5'' (see Figure 2, upper right). The lower part of the Figure provides a definition of the torsion angles in the sugar-phosphate backbone: α , β , γ , δ , ϵ , and ζ , the glycosidic torsion angle χ , and the endocyclic torsion angles ν_0 – ν_4 in the sugar ring

^{31}P). Moreover, the short-range distances are solely derived from the NOE measurements between protons. To derive a structure, the available NMR data have to be complemented by incorporating so-called holonomic constraints such as bond angles and bond lengths.

Short-range distances characteristic of typical conformations are ubiquitous in nucleic acid structures, i.e. in mononucleotide conformations as well as in the secondary structural elements, the double helices. Therefore systematic studies of short-range ^1H – ^1H distances in these structural elements have been made to serve as a basis for NMR conformational studies of nucleic acids.^{2,3} The typical short-range distances are important for spectral interpretation as well, and have been used extensively for this purpose; examples are presented below.

Similar remarks can be made with respect to the torsion angles and their corresponding J couplings. Quite reliable Karplus equations are available to relate the torsion angles to J couplings (see below). Furthermore, methods that rely on coherence transfer, thus on the value of J couplings, become increasingly important for spectral interpretation. Therefore, an overview of important coupling constants is presented in Figures 3 and 4. The ranges introduced for the three-bond coupling constants are related to their dependence on the value of the corresponding torsion angle. In view of the importance for spectral interpretation and structure determination this is discussed more extensively in the following sections. We note that of the backbone torsion angles α , β , γ , δ , ϵ and ζ , the torsion angles α and ζ cannot be determined via J coupling analysis.

Figure 2 Newman projections of the torsion angles α , β , γ , δ , ϵ , and ζ shown in the staggered conformations *gauche*-minus (g^-), *gauche*-plus (g^+), and *trans* (t). The sign convention of the angles is as follows: a positive torsion angle is obtained after a clockwise turn (about the central bond perpendicular to the paper) of the bond to the back (thick line) from the eclipsed position with bond (thick line) in the front to its present position. The glycosidic torsion angle χ is called *anti* when $\chi = 180 \pm 90^\circ$ and *syn* when $\chi = 0 \pm 90^\circ$

3.1 The Furanose Ring

The structural characterization of this moiety has attracted considerable attention, partly because of its intrinsic interest as a subject of conformational analysis, partly because its conformation is thought to be representative of the more global nucleic acid structure, e.g. compare A- and B-type helices where the sugar conformation is C-3'-*endo* vs. C-2'-*endo* respectively.

The most popular description of the furanose conformation makes use of the concept of pseudorotation which was introduced by Pitzer and collaborators⁴ to describe the conformation of cyclopentane. The application of this model to furanose rings was introduced by Altona and Sundaralingam.⁵ In this approach the 5-membered ring is characterized by two parameters, the phase angle of pseudorotation, P , and the pucker amplitude, Φ_m . For equilateral 5-membered rings the

relationship between their endocyclic torsion angles and the pseudorotational parameters is simply given by:⁵

$$\nu_j = \Phi_m \cos[P + 144(j - 2)] \quad (1)$$

where j varies from 0 to 4 and ν_j is the j^{th} torsion angle. For the nonequilateral, heterocyclic furanose ring with unequal bond distances and angles this equation has been adapted as follows:³

$$\Phi_{1'2'} = 121.4 + 1.03\Phi_m \cos(P - 144) \quad (2a)$$

$$\Phi_{1'2''} = 0.9 + 1.02\Phi_m \cos(P - 144) \quad (2b)$$

$$\Phi_{2'3'} = 2.4 + 1.06\Phi_m \cos(P) \quad (2c)$$

$$\Phi_{2''3'} = 122.9 + 1.06\Phi_m \cos(P) \quad (2d)$$

$$\Phi_{3'4'} = -124.0 + 1.09\Phi_m \cos(P + 144) \quad (2e)$$

The Φ_{ij} terms are the torsion angles defined by the protons of the sugar ring. With this parameterization a satisfactory description can be provided of the furanose conformation. Values of P around the C-2'-*endo* conformation, the so-called S conformation, amount to 140 – 180° , and values of P around the C-3'-*endo* conformation, the so-called N conformation, amount to 0 – 40° .

An exact description of 5-membered ring conformations, which accounts for changes in bond distances and angles when the pseudorotation cycle of the furanose is traversed, has been given recently.^{6,7} The impact and importance of this more complete approach on and for NMR-derived structures has not yet been explored.

3.2 Torsion Angle β

The J couplings defining β are summarized in Table 2. Examination of Figure 3 shows that ${}^3J\{P(n), C-4'(n)\}$ may vary between 1 and 11 Hz. Low values (≈ 1 Hz) of ${}^3J\{P(n), C-4'(n)\}$ are only obtained when β is in the g^+ or g^- domain. These are energetically unfavorable rotamers. Commonly, β resides in the *trans* domain and the coupling constant is then found between 7 and 11 Hz. Interestingly, when β is in the g^- or g^+ range ${}^3J\{P(n), H-5'(n)\}$ or ${}^3J\{P(n), H-5''(n)\}$ becomes quite large, i.e. approaches 23 Hz (see Figure 3). On the other hand, when β is in the *trans* domain these coupling constants are rather small but, for standard A- and B-helices, still sufficiently different to be useful as structural diagnostic tools (see below). Finally, it is mentioned that the four-bond coupling, ${}^4J\{P(n), H-4'(n)\}$, depends on the conformation of the sequence P–O–C-5'–C-4'–H-4'. When it takes on a W shape, i.e. a planar geometry, the coupling constant may approach a value of 3 Hz; for this to happen β needs to be in the *trans* and γ in the g^+ domain.

Figure 3 J coupling constants between different nuclei in the sugar–phosphate backbone, in the sugar moiety, and in the uridine base, which serve as a basis for coherence transfer experiments. J couplings for which a range of values is indicated depend on the torsion angle. In the lower figure (UMP) the J couplings are taken from the literature²⁹ and checked where possible and revised when necessary based on NMR measurements on a ¹³C and ¹⁵N enriched UMP mononucleotide. UMP = uridine 5'-phosphate. Note that the C numberings are only depicted as subscripts *within* the Figure, e.g. C₆ in Figure ≡ C-6 in text

Figure 4 J coupling constants found in the different bases. The J couplings in uracil and adenine have been checked and revised when necessary, based on NMR measurements on ^{13}C and ^{15}N enriched UMP and AMP mononucleotides, respectively. Those coupling constants that depend on pH are indicated for two different pH values. Note that the C numberings are only depicted as subscripts *within* the Figure, e.g. C_6 in Figure $\equiv$ C-6 in text

Table 2 J Couplings Between Nuclei, Monitoring Backbone Torsion Angles

Torsion angle	J coupled nuclei			
α	—	—	—	—
β	C-4'P-5	H-5'P-5	H-5''P-5	—
γ	H-4'H-5'	H-4'H-5''	C-3'H-5'	C-3'H-5''
δ	H-3'H-4'	C-5'H-3'	C-5'C-2'	—
ϵ	H-3'P-3	C-4'P-3	C-2'P-3	—
ζ	—	—	—	—
χ	—	—	—	—

3.3 Torsion Angle γ

This torsion angle can be monitored by $^3J\{\text{H-4}'(n),\text{H-5}'(n)\}$, $^3J\{\text{H-4}'(n),\text{H-5}''(n)\}$, $^3J\{\text{C-3}'(n),\text{H-5}'(n)\}$ and $^3J\{\text{C-3}'(n),\text{H-5}''(n)\}$ (see Table 2). Determination of the value of γ is only possible when a stereospecific assignment of the H-5' and H-5'' resonances can be achieved. It is mentioned in passing that

the two-bond couplings $^2J\{\text{H-4}'(n),\text{C-5}'(n)\}$, $^2J\{\text{C-4}'(n),\text{H-5}'(n)\}$, and $^2J\{\text{C-4}'(n),\text{H-5}''(n)\}$ also depend on γ and can aid in the identification of the H-5' and H-5'' resonances. Both topics are discussed in Section 4.4 dealing with stereospecific assignments.

3.4 Torsion Angle δ

This torsion angle is determined by the conformation of the furanose ring, i.e. by the angle of pseudorotation and the pucker amplitude. Once these have been established δ can be deduced.³

3.5 Torsion Angle ϵ

The J couplings that monitor this torsion angle are collected in Table 2. $^3J\{\text{H-3}'(n),\text{P}(n+1)\}$ is not particularly informative for an analysis of ϵ . The two rotamers about

epsilon usually considered are ϵ' and ϵ^- and these are more or less symmetrically positioned with respect to the H-3'-C-3'-O-3'-P angle, rendering this J coupling less suitable for a distinction between the two conformations. Similar to the situation encountered for β , the coupling constant ${}^3J\{P(n+1), C-4'(n)\}$ may increase from 1 to 11 Hz when ϵ decreases from 300° to 180° , i.e. ϵ changes from ϵ^- to ϵ' . It is important to observe that, simultaneously, ${}^3J\{P(n+1), C-2'(n)\}$ decreases from 11 to 1 Hz. A change from ϵ^- to ϵ' is also monitored by the four-bond coupling ${}^4J\{P(n+1), H-2'(n)\}$. When the sequence H-2'-C-2'-C-3'-O-3'-P adopts a W shape, which is only possible when ϵ is in the g^- domain and the sugar adopts an S pucker, the coupling constant approaches 3 Hz.

4 SPECTRAL INTERPRETATION

4.1 The NOE-Based Approach

Originally, systematic studies of the spectra of 'larger' nucleic acid molecules were focused on the imino proton resonances, e.g. of double helical DNA fragments and transfer RNA (tRNA) molecules. Successful interpretation of these spectra was initially achieved via the use of one-dimensional NOE difference spectra and only later on the basis of two-dimensional (2D) NOE experiments.

With the advent of 2D spectroscopy, new sequential assignment procedures were devised on the basis of intra- and interresidue NOE connectivities between the sugar and base protons. This approach (crucially) depends on the assumption that the sugar-phosphate backbone conformation of the molecule under study closely resembles that found in A- and B-type double helices. In these configurations the distances between the H-1', H-2', and H-2'' on the one hand, and H-6/H-8 on the other, are all smaller than 5 Å, i.e. for the distances within a nucleotide and for the distances between the ring H-6/H-8 protons and the sugar protons of the 5'-neighboring nucleotide (see Figure 5). Use of these connectivities may lead to sequential assignment as indicated in Figure 6 for the

pathway H-8(n) $\rightarrow$ H-1'(n) $\rightarrow$ H-6($n+1$) $\rightarrow$ H-1'($n+1$) $\rightarrow$ H-8($n+2$) $\rightarrow$ H-1'($n+2$).

All sequential connectivities are steered along the individual H-6/H-8 base protons. Thus, the occurrence of overlap requires additional experiments or the trying out of alternative pathways until a selfconsistent solution is obtained. Overlap may also occur for the sugar proton resonances, but then the combined use of sequential pathways running along the H-1' or the H-2'/H-2'' resonances may help to alleviate the problem. This approach works less well for RNA molecules where the H-2'' proton is replaced by a hydroxyl group as a result of which the H-2' resonances shift to high frequency (downfield) and overlap with the other sugar proton resonances, except for the H-1' resonances. Still, most of the successful structure determinations carried out so far for nucleic acid molecules with molecular masses of up to approximately 7200 Da have followed this approach. Examples are discussed below.

4.2 Assignment Through Coherence Transfer

As mentioned the NOE-based assignment procedure depends on the structure of the single strand considered and is not guaranteed to work for unusual conformations. Therefore experiments based on coherence transfer methods have been developed that provide complementary and structurally independent information.

In nucleic acid structures several continuous networks of vicinal J couplings can be distinguished that can be used in coherence transfer experiments and may aid in the assignment and identification of individual mononucleotides and in sequential assignment. Ideally, one would like to link these networks in such a way that a complete interpretation of the spectrum could be achieved solely through the use of coherence transfer experiments. Sometimes this is very cumbersome, e.g. the J coupling between the sugar H-1' proton and the H-6/H-8 protons is so small (≈ 0.3 Hz) that only in idealized cases can their signals be correlated through coherence transfer.⁸ Then one has to rely on the NOE-based approach outlined above (see, however, assignments in isotope-enriched RNAs in Section 4.3).

Figure 5 Distances between the H-6 or H-8 ring protons of a base and the H-1', H-2', and H-2'' protons of its own sugar and of the sugar of the 5'-neighboring nucleotide for A type (a) and B type (b) helices. Note that H numberings are denoted as subscripts only *within* the Figure, e.g. H_{1'} $\equiv$ H-1'

Figure 6 Different pathways used in assignment procedures of nucleic acid spectra. The NOE pathway formed by the base ring protons and the H-1' sugar protons is indicated in blue. The coherence transfer pathways between sugar protons and phosphorus atoms in the sugar-phosphate backbone and between the protons within the sugar moiety are indicated by red arrows. Note that the C numberings are only depicted as subscripts *within* the Figure, e.g. C₆ in Figure $\equiv$ C-6 in text

Given that the connection between the base and sugar protons has been established, the sequential assignment can be continued by employing the following chain of ^1H – ^1H spin-spin couplings:

$$\left. \begin{matrix} {}^3J(1', 2') \\ {}^3J(1', 2'') \end{matrix} \right\} \rightarrow {}^3J(2', 3') \rightarrow {}^3J(3', 4') \rightarrow \left\{ \begin{matrix} {}^3J(4', 5') \\ {}^3J(4', 5'') \end{matrix} \right.$$

in the sugar ring (Figure 6). This network of spin-spin couplings can be used in COSY and TOCSY experiments to assign the sugar ring protons of individual mononucleotides. Through the identification of the H-1' or H-2'/H-2'' resonances in the sequential assignment described above, the sugar resonances may be attributed to a particular nucleotide in the sequence. In this approach the interpretation can in most cases be extended to involve the H-4' resonances. Assignment of the H-5'/H-5'' protons has been much more limited since the spectral region containing the H-4', H-5', and H-5'' resonances is so crowded. The resulting overlap is worsened by the often small chemical shift differences between the H-4', H-5', and H-5'' resonances, which places the cross peaks close to the diagonal. Interesting exceptions have been found in the strongly folded regions in hairpin loop molecules.⁹ Obviously, the problem becomes worse for larger molecules. It can, however, be (appreciably) reduced by application of homonuclear three-dimensional experiments, e.g. TOCSY–NOESY experiments have been conducted where it was possible to assign the resonances in the very crowded H-4', H-5', H-5'' spectral region by shifting the information to the better-resolved H-1', H-3', and H-2'/H-2'' region.^{3,27,28}

Subsequently, the network of coupled spins of the sugar ring can be connected to the resonances of the backbone nuclei by making use of the following chain of J couplings (see Figure 3):

$${}^3J\{\text{H-3}'(n), \text{P}(n+1)\} \rightarrow \begin{matrix} {}^3J\{\text{P}(n+1), \text{H5}'(n+1)\} \\ {}^3J\{\text{P}(n+1), \text{H-5}''(n+1)\} \\ {}^4J\{\text{P}(n+1), \text{H-4}'(n+1)\} \end{matrix}$$

which have been used in ^{31}P – ^1H hetero-double-quantum-filtered (DQF)–COSY experiments. The values of the J couplings and thus the intensity of the cross peaks depend on the backbone conformation. For the standard B-DNA backbone conformation ${}^3J\{\text{P}(n+1), \text{H-5}'(n+1)\} \approx 1 \text{ Hz}$, and ${}^3J\{\text{P}(n+1), \text{H-5}''(n+1)\} \approx 7 \text{ Hz}$. Hence, the $\text{P}(n+1)$ – $\text{H-5}'(n+1)$ connectivity generally is weak, but the $\text{P}(n+1)$ – $\text{H-5}''(n+1)$ connectivity is clearly visible in a ^{31}P – ^1H hetero-DQF–COSY spectrum. For the standard A-RNA conformation ${}^3J\{\text{P}(n+1), \text{H-5}'(n+1)\}$ as well as ${}^3J\{\text{P}(n+1), \text{H-5}''(n+1)\} \approx 2.5 \text{ Hz}$ giving rise to weak cross peaks. Yet, ^{31}P – ^1H hetero-DQF–COSY spectra have been used to study RNA molecules.¹⁰ The four-bond coupling constant ${}^4J\{\text{P}(n+1), \text{H-4}'(n+1)\}$ achieves its maximum ($\approx 3 \text{ Hz}$) when the atoms $\text{P-O-5}'\text{-C-5}'\text{-C-4}'\text{-H-4}'$ lie in the same plane and form a W shaped conformation (see above). This situation is approached in the standard B-DNA but not in the A-RNA backbone conformation. To our knowledge connectivities between $\text{H-4}'(n)$ and $\text{P}(n+1)$ have not been observed, the reason being that the backbone atom sequence $\text{H-4}'\text{-C-4}'\text{-C-3}'\text{-O-3}'\text{-P}$ does not form the mentioned W shape required to generate a sufficiently large four-bond J coupling. This would require that

the torsion angle ϵ falls in the g^+ domain, which is forbidden on steric grounds.

Strong overlap of the phosphate, on the one hand, and the sugar H-4' on the other hand, and H-5'/H-5'' resonances have limited the application of the described approach to 'smaller' molecules. However, recently, improved probe technology has allowed the use of hetero-TOCSY experiments or variants thereof,¹¹ and the aforementioned limitation has been overcome to a significant extent by being able to correlate ³¹P resonances with the better resolved sugar resonances, e.g. the H-1' or H-3' resonances, in analogy with the homonuclear TOCSY–NOESY experiments (see above). This approach has been successfully demonstrated for the double helix formed by the so-called Dickerson dodecamer, d(CGCGAATTCGCG) (d = deoxy, A = adenosine, C = cytidine, G = guanosine, T = ribosylthymine). The H-3' sugar resonances are quite well resolved and on the basis of H-3'(n) → P(n + 1) → H-3'(n + 1) sequential connectivities, ³¹P assignments could be established without prior knowledge of ¹H resonance assignments.¹¹ A drawback of most ¹H, ³¹P correlation methods is their limited sensitivity, which is a consequence of the large number of possible transfer routes. This leads to destructive interference during the transfer and 'dilutes' the amount of coherence giving rise to detectable signal.

4.3 Sequential Assignment of Isotope-Enriched RNAs

NMR structural studies of proteins have benefitted enormously from the use of uniformly ¹³C and ¹⁵N isotope-enriched material. In combination with newly developed pulse sequences, which specifically take advantage of these heteronuclei (see *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR* and *Three- and Four-Dimensional Heteronuclear Magnetic Resonance*), it has been possible to assign completely the spectrum of polypeptides, even for proteins with a chain length of 270 amino acids.

Recently, methods for isotope enrichment of RNA have also become available and the production of well-defined, uniformly enriched fragments is now feasible on a more or less routine basis.¹² Hopefully, in the near future, this will also be feasible for DNA molecules. In analogy with the developments in ¹H NMR, suitable pulse sequences have been or are being developed to broaden the basis for the interpretation of nucleic acid spectra, in particular those of larger molecules.

4.3.1 The NOE-Based Approach

The approach is very similar to what has been discussed earlier for nonenriched nucleic acids. The difference lies in the possibility of achieving more resolution by using ¹³C-edited NOESY spectra, which can be obtained from NOESY–HMQC or HMQC–NOESY experiments (see *Three-Dimensional HMQC–NOESY, NOESY–HMQC, and NOESY–HSQC*). Similarly, for imino and amino resonances ¹⁵N-edited NOESY spectra can be acquired with increased resolution.¹³

4.3.2 Coherence Transfer

For ¹³C and ¹⁵N isotope-enriched RNA a complete spectral interpretation can basically be obtained solely through the use

of coherence transfer pathways. These have been sketched in Figure 3 in the form of a network of J couplings in the sugar phosphate backbone and in the sugar ring, and a combination of J couplings connecting the sugar ring to the bases. To a large extent these coherence pathways are complementary to those in nonenriched RNA, but the presence of the isotopes allows the development of more powerful methods for spectral interpretation, in analogy with ¹H NMR. Thus, uniform ¹³C enrichment of RNA allows for an extension of the sequential assignment of the backbone resonances discussed above by involving the ¹³C spins.

This has been demonstrated in a three-dimensional so-called HCP experiment.¹⁴ In this experiment ¹H coherence is transferred into ¹³C coherence using the direct $J(^{13}\text{C}, ^1\text{H})$ coupling. Subsequently, ¹³C coherence is transferred into ³¹P coherence and then, via the reverse route, this coherence is transferred back into ¹H coherence. In the HCP experiment, therefore, the following correlation can be found: C-4'(n) → P-3'(n + 1) → H-4'(n), C-4'(n) → P-5'(n) → H-4'(n), C-5'(n) → P-5'(n) → H-5'/H-5''(n), C-3'(n) → P-3'(n + 1) → H-3'(n). This allows a sequential walk along the backbone using the C-4'(n) → P(n + 1) → C-4'(n + 1) correlations (see Figure 7). In the process assignments are also obtained for the C-3' and C-5' resonances, alongside those for the H-3', H-4' and H-5'/H-5'' resonances. In case the torsion angle ϵ is shifted to the g^- domain, the pathway C-4'(n) → P(n + 1) becomes blocked. Then concomitantly the pathway C-2'(n) → P(n + 1) becomes available and can be used as a detour in the sequential assignment procedure (Figure 3).

In the next step the backbone resonances can be connected to the sugar ring resonances through so-called H–C–H experiments in which coherence is transferred along the indicated pathway. The power of this approach has been demonstrated by Nikonowicz and Pardi using INEPT transfer.¹³ A more sensitive approach is provided through CCH TOCSY experiments in which the transfer step from C → H is achieved via cross polarization instead of INEPT.¹⁴

Correlation between signals of the sugar ring and the base by means of coherence transfer, which as mentioned in the preceding section is difficult to achieve for nonenriched material, can be conveniently established for doubly labeled ¹³C- and ¹⁵N-enriched material in a three-dimensional so-called HCN experiment. Use is made of the coupling pathway

$$J(\text{H-1}', \text{C-1}') \Rightarrow \begin{cases} (\text{C-1}', \text{N-9}) \Leftrightarrow J(\text{N-9}, \text{C-8}) \\ \Rightarrow J(\text{C-8}, \text{H-8}) \text{ (for purines)} \\ J(\text{C-1}', \text{N-1}) \Leftrightarrow J(\text{N-1}, \text{C-6}) \\ \Rightarrow J(\text{C-6}, \text{H-6}) \text{ (for pyrimidines)} \end{cases}$$

Successful experiments have been performed on a 30-mer RNA molecule which contains the binding site for the Rev protein encoded by Human Immunodeficiency Virus.¹⁵ The intranucleotide H-1'–H-6/H-8 connectivities obtained in this experiment allow for a distinction of intra- and internucleotide H-1'–H-6/H-8 NOE cross peaks in NOESY experiments.

The J couplings between the spins in the bases form a complicated network (see Figures 3 and 4). In some cases they are large enough to allow the assignment of the signals of the rest of the nuclei in the ring. For example in cytidine

Figure 7 Cross sections through the three-dimensional HCP spectrum at the positions of the C-4' and C-5' resonances of the individual nucleotides of the hairpin formed by r(GGGCC-AAAGCCU) (r = ribose). The C-4' planes show the sequential walk through the sugar-phosphate backbone from the first residue G1 (at the 5'-end) to the final residue U12 (at the 3'-end) as indicated by the arrows and the drawn lines. The two cross peaks marked by asterisks in the C-5'(i) planes indicate the H-5'/H-5'' resonance positions of residue *i*; the dotted line connects these H-5'/H-5'' cross peaks with the P-5' cross peak in the C-4'(i) plane

and uridine the ^{13}C resonances of C-4, C-5, and C-6 are easily identified in this manner (Figure 4).

4.4 Stereospecific Assignment

Important for structure determination is the stereospecific assignment of resonances. In nucleic acids this concerns H-5'/H-5'' and, only in DNA, also the H-2'/H-2'' resonances. The latter pair generally does not present too many problems. In the absence of spin diffusion the H-1'-H-2'' NOE cross peak is always more intense than the H-1'-H-2' cross peak, independent of the sugar pucker. The values of $J(\text{H-1}',\text{H-2}')$ and $J(\text{H-1}',\text{H-2}'')$ vary with the sugar conformation. In the N state $J(\text{H-1}',\text{H-2}') \leq 1\text{ Hz}$ and much smaller than $J(\text{H-1}',\text{H-2}'')$. For the S conformation, however, $J(\text{H-1}',\text{H-2}') > J(\text{H-1}',\text{H-2}'')$.^{3,5}

The stereospecific assignment of the H-5'/H-5'' resonances is, however, more involved. For regular double-helical structures H-5'' resonates to low frequency of H-5'.³ For more irregular structures this need not be the case. Then by a combination of $J(\text{H-4}',\text{H-5}'/\text{H-5}'')$ couplings and Overhauser effects between H-3' and H-5'/H-5'' and between H-4' and H-5'/H-5'' the relative positions of these signals can be established.^{8,9} In this approach the stereospecific assignment is intimately related to the determination of the value of the torsion angle γ .

Introduction of ^{13}C enrichment offers an elegant and perhaps more reliable approach to the problem. It has been recognized that the two-bond couplings $^2J(\text{C,H})$ in the system $\text{H}-\text{C}-^{13}\text{C}-\text{X}$, where X is an electronegative atom, depend on the torsion angle θ defined by the mutual orientation of H and X. Thus, for ethanol it was found that $^2J(\text{C,H})$ is negative for $0^\circ \leq \theta < 90^\circ$ and positive for $90^\circ < \theta \leq 180^\circ$, with maximum absolute values at 0° and 180° . Adopting these results for the torsion angle defined by $\text{O-5}'-\text{C-5}'-\text{C-4}'-\text{H-4}'$, the relative signs of the coupling constants $J(\text{C-4}',\text{H-5}')$, $J(\text{C-4}',\text{H-5}'')$, and $J(\text{C-5}',\text{H-4}')$ can be measured, and the stagger of γ as well as the stereospecific assignment become directly available.¹⁶ It is noted in passing that this approach can also be used to establish the pucker of the sugar ring.

5 STRUCTURE DETERMINATION

After the development of multidimensional NMR techniques and the invention of reliable resonance assignment procedures, a burst of activities ensued in investigations of nucleic acid structure. By the end of 1988 a great number of different species including canonical double helices, double helices with mismatches, with bulges, and with chemically modified bases, and double helices complexed to drugs, had been studied extensively. Mostly, these studies were conducted on a more qualitative level of interpretation of the spectral parameters. Subsequently, methods permitting a more quantitative handling of the spectral data became available leading to improved structure determination.

The distribution of protons in nucleic acids that can be used for structure determination is rather unevenly divided. The sugar moiety is most blessed with protons but their value for a conformational analysis of the ring is strongly limited.¹⁷ In fact J couplings play a major role in the derivation of its structure.^{5,17} In the bases, there is a relative paucity of protons,

which often renders a determination of their orientation with respect to their surroundings more difficult. Definition of a reliable structure therefore necessitates the deduction of accurate proton distances from available NOEs, and a range of different programs that account for spin diffusion (IRMA, MARDIGRAS, NO2DI, MORASS)³ have been developed to achieve this purpose (see *Nucleic Acid Structures in Solution: Sequence Dependence*). Additionally, J coupling information remains to be required for a proper structure elucidation, especially for the sugar ring, and also for the sugar-phosphate backbone. For instance, the J couplings $J(\text{H-1}',\text{H-2}')$, $J(\text{H-2}'',\text{H-3}')$, and $J(\text{H-3}',\text{H-4}')$ are good monitors of the sugar conformation.³ Reliable Karplus equations, summarized in Table 3, are available to relate J couplings to torsion angles for the deduction of the sugar ring structure, and also for the determination of the sugar-phosphate backbone.

Applications of these methods have led to more quantitative structural NMR studies. Here we describe some results obtained for hairpin molecules and show that insights into rules of folding emerge on the basis of such studies. Elsewhere in this Encyclopedia other nucleic acid structures are considered (*DNA Triplexes, Quadruplexes, and Aptamers* and *Nucleic Acid Structures in Solution: Sequence Dependence*).

6 HAIRPIN STRUCTURES

Hairpins have received a great deal of attention in NMR structural studies. Most of the investigated molecules exhibit a reasonably well-defined structure, but this may have more to do with the particular choice of the systems used in these NMR studies than with a general phenomenon of hairpin loops always being structured.

The choice of RNA hairpins in these investigations was very much dictated by the results of phylogenetic comparisons of ribosomal and of messenger RNA, which showed a strong preference for the occurrence of 4-membered loops with distinct, conserved sequences. Interestingly, many of these conserved sequences, e.g. -UUCG- (U = uridine), -UACG-, and -GAAA-, were found to render the hairpins unusually stable.¹⁸ In DNA studies the choice was guided by the discovery of unexpectedly stable 'minihairpins',¹⁹⁻²¹ by theoretical considerations that 4-membered loops would be most stable, and that stability would be increased by the formation of a base pair between the first and the last base of the loop.^{9,22}

A number of hairpins have now been subjected to quantitative structural studies. Here we consider two examples, one hairpin formed by the sequence $\text{d}(\text{A}_1\text{T}_2\text{C}_3\text{C}_4\text{T}_5\text{A}_6-\text{T}_7\text{T}_8\text{T}_9\text{A}_{10}-\text{T}_{11}\text{A}_{12}\text{G}_{13}\text{G}_{14}\text{A}_{15}\text{T}_{16})$ the other by $\text{d}(\text{A}_1\text{T}_2\text{C}_3\text{C}_4\text{T}_5\text{A}_6-\text{G}_7\text{T}_8\text{T}_9\text{A}_{10}-\text{T}_{11}\text{A}_{12}\text{G}_{13}\text{G}_{14}\text{A}_{15}\text{T}_{16})$, which are typical of the 4-membered hairpins studied to date. In both cases the three-dimensional structure was obtained on the basis of available NMR distance and torsion angle constraints and on a multiconformational analysis approach (the -TTTA- hairpin) or a variable target function and a molecular dynamics approach (the -GTTA- hairpin) followed in both cases by unconstrained energy minimization. In the process the results were checked by back calculation of the NOESY spectrum. The structures of these hairpins are presented in Figure 8. In both hairpins, the loops exhibit a compact folding pattern. The first and the last base form noncanonical base pairs, in the -TTTA- loop a

Table 3 Karplus Equations for Relationships Between Torsion Angles, Φ (deg), and J Couplings (Hz)^a

$$^3J(^1\text{H}, ^1\text{H}) = 13.7 \cos^2 \Phi - 0.73 \cos \Phi - \sum \Delta\chi_i [0.56 - 2.47 \cos^2(\xi_i \Phi + 16.9|\Delta\chi_i|)] + \Delta J \quad (3a)$$

$$^3J(^1\text{H} \text{ CO}^{31}\text{P}) = 15.3 \cos^2 \Phi - 6.2 \cos \Phi + 1.5 \quad (3b)$$

$$^3J(^{13}\text{C} \text{ CO}^{31}\text{P}) = 8.0 \cos^2 \Phi - 3.4 \cos \Phi + 0.5 \quad (3c)$$

The meanings of the symbols in ¹ are as follows:

$$\Delta\chi_i = \Delta\chi_{i,\alpha} - 0.14 \sum \Delta\chi_{ij,\beta}$$

$\Delta\chi_{i,\alpha}$, $\Delta\chi_{ij,\beta}$: Huggins electronegativity difference between α or β substituents and H, with $\Delta\chi_{i,\alpha}$, $\Delta\chi_{ij,\beta} = 1.3(\text{O})$, $0.4(\text{C})$, $0.85(\text{N})$, $-0.05(\text{P})$.

ξ_i : relative orientation factor of substituents. In the Newman projection of H-a, S-1 α , S-3 α -C-1-C-2, S-2 α , S-4 α , H-b: S-1 α has a positive position, $\xi_i = +1$, if H-a-C-1-S-1 $\alpha = 120^\circ$, a negative position, $\xi_i = -1$, if angle = -120° .

$$\Delta J: -2.0 \cos(P - 234) \text{ for } 144^\circ < P < 324^\circ \text{ for } J(\text{H-1}', \text{H-2}')$$

$$-0.5 \cos(P - 288) \text{ for } 198^\circ < P < 360^\circ \text{ and } 0^\circ < P < 18^\circ \text{ for } J(\text{H-2}', \text{H-3}').$$

In all other cases $\Delta J = 0.0$

^aThe constants in ¹ are average values. For more accurate numbers the reader is referred to the literature.^{3,23}

T.A Hoogsteen pair and in the -GTTA-loop a G.A pair of the form indicated in Figure 8. The disposition of the second base is characteristic of two classes of 4-membered hairpin loops so far encountered, i.e. in the -TTTA- loop this base is turned into the minor groove and in the -GTTA- loop stacks upon the first base. After the third residue the sugar-phosphate backbone exhibits a sharp turn essentially changing its direction by 180° . Finally, as mentioned, the base of the fourth residue turns into the loop to form a base pair with the first. These features are common to a number of well-defined hairpins.²⁴ Depending on the sequence of the 4-membered loop, a base pair is formed between the first and the last base of the loop. A cytidine in the 5'- and a guanine in the 3'-terminal position of the loop form a normal Watson-Crick CG base pair. Other combinations of terminal bases turn out to form noncanonical base pairs. Given complementary bases, base pair formation is facile for a pyrimidine at the 5'- and a purine at the 3'-end of the loop, but not the other way around. A purine in the 5'- and a pyrimidine in the 3'-position hinders, but does not strictly forbid, the formation of a base pair. However, destabilization of the hairpin is observed with respect to its counterpart, i.e. with respect to the hairpin with a pyrimidine at the 5'- and a purine at the 3'-end of the loop.

For the 4-membered loops two different folding classes emerge. They are exemplified by the two hairpin structures described above. In one class the second loop residue is turned into the minor groove and in the other the first three bases continue to stack on the stem although the position of the third base is often less well-defined.

In a hairpin the two chains of the stem which run in opposite directions are connected by the loop in which the change of directionality of the phosphate backbone is located. It turns out that in most cases the course of the backbone is altered abruptly by one sharp turn between two nucleotides. For DNA hairpins this turn is found between the third and the fourth base (nucleotide) in the loop, even in the aforementioned two different classes of loop folding. In the sharp turn the torsion angle γ has always been found in the *trans* domain while its neighbor β remains in the normal *trans* domain or changes to

the g^+ domain, but only for about 50% of the time. For RNA the situation is as yet less well-defined. For the two examples available the sharp turn occurs between either the first and the second or the third and the fourth residue.²⁴

7 DYNAMICS

There is overwhelming evidence for the occurrence of conformational heterogeneity and internal mobility of nucleic acids. Developments up to 1989 have been reviewed.¹⁷ The perhaps most simple example is the rotation of the methyl groups in thymines. Its influence on the dipole-dipole relaxation and thus on the intensity of nuclear Overhauser effects has been analyzed extensively. It is important to make a distinction between situations in which methyl rotation is fast and in which it is slow with respect to the molecular tumbling. In the first case, averaging of the distance of the methyl protons to some other neighboring proton shows up as $\langle 1/r^3 \rangle^2$, and in the latter case as $\langle 1/r^6 \rangle$ in the spectral density function.

In particular, double-helical DNA fragments have been subjected to NMR relaxation studies, and here use has been made of ¹H nuclei, and also the relaxation properties of ²H, ¹³C, and ³¹P have been studied. In general a rigid rod model turns out to be inadequate to account for the observed relaxation rates. Phosphorus-31 investigations of DNA fragments of 150–500 base pairs long reveal motions of the phosphate groups taking place on the nanosecond timescale. Carbon-13 relaxation studies have indicated that the (deoxy)ribose units exhibit an enhanced mobility relative to the bases, but it seems that some base motions such as propeller twisting and tilting have little effect on ¹³C relaxation.

As mentioned, the determination of the sugar conformation is most reliably performed via a J coupling analysis. Very often, however, it is not possible to obtain a set of coupling constants that is consistent with one particular sugar conformation. This observation has been interpreted to arise from the coexistence of two conformations in the

Figure 8 Structural models of the hairpins formed by d(ATCCTA-TTTA-TAGGAT) and d(ATCCTA-GTTA-TAGGAT). (a) A view of the hairpin with the -TTTA- loop in which the helix axis is in the plane of the Figure. The green base is part of the second loop residue which folds into the minor groove. The Hoogsteen T.A base pair (see text) and the third loop residue are indicated in blue. An alternative view is given in (b) where the structure is viewed along the helix axis. The Hoogsteen T.A base pair is indicated in green. The manner in which the third thymidine in the loop stacks upon this base pair is indicated. (c) The structure of the hairpin with the -GTTA- loop, viewed perpendicular to the helix axis. In this molecule the second loop residue (in blue) stacks upon the G.A base pair (in blue). (d) The molecule viewed along the helix axis; it is clear that the second residue (in red) stacks upon the guanine base of the G.A base pair (in green)

aforementioned N- and S-domains (see Section 3.1), which are in rapid equilibrium with one another. The observed J couplings then are the weighted average of the J couplings in the N- and S-conformations:

$$J_{\text{obs}} = f_N J_N + f_S J_S \quad (3)$$

where J_{obs} stands for the observed coupling constant, J_N and J_S for the coupling constants in the N- and S-conformation, respectively, and f_N and f_S are the fraction of the N- and S-conformers, respectively. So far no exhaustive studies have been conducted of the percentages of the occurrence of N- and S-conformations as a function of sequence and structure. However, it has been found that sugar rings in B-DNA duplexes seldom display 100% S type conformational purity. Purine residues approach this situation more closely than pyrimidine residues, i.e. on average one finds that the fraction of S conformers $f_S \approx 90\%$, whereas for pyrimidines $f_S \approx 78\%$.²³

Considerable attention has been devoted to imino proton relaxation. At low temperatures and low pH the relaxation is dominated by dipolar interactions, whereas at higher temperatures exchange of the imino protons becomes increasingly important. The dipolar relaxation studied in B type and Z type helices indicates bending of the double helix and out-of-plane motion of the bases. This is also suggested by ^2H relaxation data of $\text{G}(\text{D}_2\text{H}_8)$ deuterated calf-thymus DNA. The data can, however, also be explained by a 'jumping in a cone' model. This exemplifies a more general aspect of NMR relaxation studies: relaxation data can often be accounted for by different models.

For a quantitative measure of local motion a 'model-free description' has been developed but in this approach only the timescale, orientation, and amplitude of the motion can be determined.

The exchange observed for the imino protons at higher temperatures provides insight into the lifetimes of the base pairs; this subject has been reviewed recently.²⁵ There is a strong consensus of opinion that the transfer of imino protons in the base pair to water is mediated through an open state. Thus, to relate the lifetime of the base pair to the relaxation properties of the imino protons (at least) a three-site exchange problem has to be considered. However, addition of a suitable catalyst often enhances the imino proton exchange rate and it can be shown that for high (infinite) catalyst concentration the transfer rate is a direct measure of the base pair lifetime. Based on this approach Guéron and collaborators²⁵ found in a series of 20 B-DNA duplexes that, at 15 °C, the lifetime of A-T base pairs is in the range of 0.7–7 ms and that of G-C pairs in the range of 5–50 ms. This may change in molecules with particular sequences, in drug-DNA complexes or in more complicated molecules. Thus, in Z-DNA the base pair lifetimes are 2 orders of magnitude longer than in B-DNA. The observation that in A-T tracts containing DNA the lifetime of A-T pairs may be significantly longer than in normal B-DNA is of considerable interest. The tRNA molecule is an example where the base pair lifetime may vary between milliseconds and minutes. Studies of d(TCCCCC) and related deoxycytidine-rich sequences conducted at low pH showed that these molecules form remarkable structures consisting of two parallel-stranded duplexes with C-C⁺ base pairs that form tetrads through interdigitation.²⁶ In the tetraplex the two

duplexes are in an antiparallel orientation. The intercalation sites generated at every base pair in each duplex allow alternate stacking of the C-C⁺ base pairs from the duplexes. Base pair lifetimes of this complex are comparable to the longest lifetimes observed in tRNA. It is also interesting to mention that the imino proton in the C-C⁺ base pair switches between the two bases at a rate larger than 80 000 s⁻¹.

Attempts have been made to establish and describe the physical motion of the base pair opening event, and to find out whether the disruption of base pairs takes place independently, i.e. as an independent fluctuation of the equilibrium structure, or coupled to bending or twisting motions of the DNA helix. An interesting pathway in which a base rotates toward the major groove around an axis that is parallel to the helix axis and intersects the sugar moiety, has been proposed by Ramstein and Lavery.²⁵ This proposal, as well as suggestions in which base pair opening is a feature of long-range fluctuations of the double helix, await experimental verification.

1 INTRODUCTION

Isotopic substitution is the smallest perturbation that may be introduced into a molecule without changing the chemical properties of a molecule. This property of isotopic substitution is of particular importance in biological studies where small structural differences in molecules can dramatically alter the biological effects. One isotope that is extremely useful in biological NMR studies involving oxygen is ^{18}O . Oxygen-18 is an NMR-inactive isotope. As a result, the effect of ^{18}O on NMR-active nuclei is classified as an intrinsic secondary isotope effect because ^{18}O isotopic substitution changes the shielding of other nuclei in the molecule. Therefore, the NMR signals of chemically identical nuclei for ^{16}O and ^{18}O isotopomers will have different chemical shifts. In general, the chemical shifts of nuclei in ^{18}O isotopomers will be at a lower frequency than the ^{16}O isotopomers, and thus the heavier isotope shields the nuclei. The natural abundances of the oxygen isotopes are 99.76% ^{16}O , 0.04% ^{17}O , and 0.20% ^{18}O . Therefore, the magnitudes of this secondary isotope effect are often measured relative to the ^{16}O isotopomers by calculating the differences between the chemical shifts of the two isotopomers, and are called ('upfield') ' ^{18}O isotope shifts' (or 'isotope-induced shifts', or 'isotope effects'). A chemical shift for ^{18}O isotopomers at lower frequency would imply that these 'upfield' ^{18}O isotope shifts have negative values. However, both negative and positive values have been used for the isotope shifts. Therefore, unless otherwise indicated, it should be assumed that the ^{18}O isotope shifts are to lower frequency regardless of the convention utilized in a specific paper to calculate the isotope shift. Because the magnitude of the ^{18}O isotope shifts are field dependent, they are properly reported in chemical shift terms (ppm) and not hertz.

^{18}O isotope shifts have been reported for 14 NMR nuclei: ^1H , ^{13}C , ^{15}N , ^{17}O , ^{29}Si , ^{31}P , ^{51}V , ^{53}Cr , ^{55}Mn , ^{93}Nb , ^{95}Mo , ^{99}Tc , ^{129}Xe , and ^{195}Pt .¹ The first ^{18}O isotope shift was reported in 1970 in ^1H NMR. It was not until later that ^{18}O isotope shifts for other nuclei were reported: ^{55}Mn in 1976, ^{95}Mo in 1977, ^{31}P in 1978, ^{13}C in 1979, and the remainder in 1981–87. Therefore, the intrinsic secondary isotope effect of ^{18}O in NMR spectroscopy is a fairly recently known phenomenon, but it has made a significant contribution in biological NMR.

The ^{18}O isotope shifts that have been of greatest importance in biological NMR are in ^{13}C NMR, ^{15}N NMR, and ^{31}P NMR; each of these is discussed here following a brief description of the general properties of the ^{18}O isotope shifts.

2 PROPERTIES OF THE ^{18}O ISOTOPE SHIFTS IN NMR

There are a number of general properties for the different ^{18}O isotope shifts in NMR. The magnitudes of the isotope shifts are small relative to the chemical shift range for the NMR nuclide. In general, the ^{18}O isotope shifts are less than 1 ppm, and are more conveniently referred to in parts per billion (ppb; 1 ppb = 0.001 ppm). The smallest isotope shift that has been reported is 0.93 ppb in ^{13}C NMR in dimethylmaleic anhydride, and the largest isotope shift is 100₀ ppb (per ^{18}O) in ^{195}Pt NMR for tetraaquaplatinum(II). The one-bond and long-range (two or more bonds) chemical shifts for all the ^{18}O isotopomers are at a lower frequency (upfield), except for two long-range effects reported in ^{13}C NMR over three bonds in 2,6-dimethyl-4-pyrone² and over four bonds in artemisinin³ where shifts to higher frequency (downfield) were observed. The magnitude of an ^{18}O isotope shift is highly dependent on the structure of the functional group; this is most clearly seen in the ^{18}O isotope shifts in ^{13}C NMR, ^{15}N NMR, and ^{31}P NMR, where studies of the relationship between the structure of the functional groups and the isotope shifts have been most complete.^{1,4} The magnitudes of ^{18}O isotope shifts are additive over one bond and long range, and, in general, are temperature independent and sometimes exhibit a small solvent dependence. Oxyanions, for example phosphate and carboxylates, show a significant pH dependence for the ^{18}O isotope shifts that reaches a maximum near the pK_a of the acid. Finally, symmetrical molecules such as succinic acid, pyrophosphate, and dimethylglyoxime can have their chemical shift equivalence removed by asymmetrical ^{18}O isotopic substitution; this can result in the transformation of a simple NMR spectrum into a very strongly coupled AB pattern when the magnitude of the ^{18}O isotope shift is small relative to the magnitude of the scalar coupling constant.

Because the natural abundance of ^{18}O is very small (0.20%), observation of ^{18}O isotope shifts at natural abundance on NMR-active nuclei have been reported only under ultrahigh resolution conditions in a few rare instances. Highly enriched $^{18}\text{O}_2$ and H_2^{18}O (up to approximately 99 atom % ^{18}O) are commercially available, as well as other highly enriched ^{18}O compounds. Generally, these compounds are used to synthesize ^{18}O -labeled compounds of NMR-active nuclei at natural abundance or using molecules enriched in the NMR nuclei. Basic outlines of experimental procedures to follow in studies utilizing the ^{18}O isotope shifts in ^{13}C NMR and ^{15}N NMR⁵ and in ^{31}P NMR⁶ have been described. A very important property of the ^{18}O isotopomers is that the spin–lattice relaxation time (T_1) is not changed.

Some of these properties are illustrated in Figures 1 and 2. One-bond, long-range, and the additivity of the ^{18}O isotope shifts are illustrated in Figure 1 at natural abundance ^{13}C NMR in the six ^{16}O and ^{18}O isotopomers of dimethylmaleic anhydride [Figure 1(c)].⁷ The ^{13}C NMR signals for the alkenic carbon atoms [Figure 1(a)] and the carbonyl carbon atoms

Figure 1 The natural abundance ^{13}C NMR spectrum of 53% ^{18}O -labeled dimethylmaleic anhydride shows one-bond and long-range ^{18}O isotope shifts of (a) the alkenic carbon region and (b) the carbonyl carbon region. The six ^{16}O , ^{18}O isotopomers are given in (c), where ^{18}O is denoted by solid circles. The peak assignments are indicated by a letter for the isotopomer and a number for the carbon atom in that molecule. Symmetrical isotopomers (a, c, e, and f) have only one signal in each region, while asymmetrical isotopomers (b and d) have two signals in each region. The signals for the alkenic carbon (carbon atoms 2 and 3) and for the carbonyl carbon (carbon atoms 1 and 4) of the ^{16}O isotopomer (species a) are assigned a value of 0 ppm; the signals to the left in (a) and (b) are the C-1 of citraconic anhydride and the quaternary carbon of benzyl alcohol, respectively, added as internal standards to preclude the possibility of fine splittings arising from magnetic field inhomogeneities. The values for the ^{18}O isotope shifts observed in the spectrum are given in ppb in (d) as positive numbers for upfield shifts. (Reprinted by permission of the American Chemical Society from T. L. Mega and R. L. Van Etten, *J. Am. Chem. Soc.*, 1993, **115**, 12 056)

[Figure 1(b)] clearly show individual NMR signals for each of the isotopic species. The magnitudes of each of the ^{18}O isotope shifts are summarized in Figure 1(d). The ^{15}N NMR spectrum of ^{15}N , ^{18}O dimethylglyoxime shown in Figure 2 illustrates that asymmetrical ^{18}O isotopic substitution removes the chemical shift equivalence in a symmetrical molecule and

Figure 2 The ^{15}N NMR spectrum of dimethylglyoxime (95% ^{15}N , 27% ^{18}O) shows signals for the $(^{15}\text{N}^{16}\text{O})_2$ isotopomer at 0.0 ppm and for the $(^{15}\text{N}^{18}\text{O})_2$ isotopomer at -0.067 ppm (a low frequency shift). The asymmetrical $(^{15}\text{N}^{16}\text{O}, ^{15}\text{N}^{18}\text{O})$ isotopomer reduces the degeneracy of the magnetically equivalent nuclei to yield an AB spectrum, which is centered at -0.0335 ppm. Only the central doublet of the AB quartet is observed; the outer resonances are 1.4% of the central doublet, and therefore are buried in the baseline. The three-bond ^{15}N – ^{15}N geminal coupling constant of 5.7 Hz was calculated from the spectrum. (Reprinted by permission of the American Chemical Society from G. Rajendran, R. E. Santini, and R. L. Van Etten, *J. Am. Chem. Soc.*, 1987, **109**, 4357)

produces an AB spectrum, from which a three-bond coupling constant may be calculated.⁸

3 STUDIES UTILIZING ^{18}O ISOTOPE SHIFTS IN ^{13}C , ^{15}N , AND ^{31}P NMR

The intrinsic secondary ^{18}O isotope effects in ^{13}C NMR and ^{31}P NMR have been used widely and successfully in a broad range of studies, and have generally proven their values as primary experimental techniques. The intrinsic secondary ^{18}O isotope effect in ^{15}N NMR has not been used as extensively. There are advantages that the ^{18}O isotope shift technique has over other techniques. Analysis of a reaction mixture by NMR is direct, requiring only that the relevant NMR signals be resolved; little or no sample manipulation, such as derivatization, is generally required. Because of the dependence of the ^{18}O isotope shifts on the structures of the functional groups, positional information may be obtained directly and simultaneously at different sites in a molecule, which is important in some studies to remove ambiguities regarding the position of an oxygen atom. In numerous studies nearly continuous acquisition of kinetic data may be obtained, with a possibility of answering simultaneously more than one experimental question. For some studies, the ^{18}O isotope shifts in NMR are virtually the only technique available due to experimental restrictions imposed by other techniques that make them very difficult to use. In other studies, the ^{18}O isotope shifts in NMR may be considered to be a complementary technique to other techniques, but the particularly simple design and interpretation of the results make the use of ^{18}O isotope shifts in NMR the technique of choice. A disadvantage of ^{18}O isotope shifts in NMR is

Figure 3 The hydrolysis of sucrose in 60% [^{18}O]water at pH 2.9 and 80°C was followed as a function of time using natural abundance ^{13}C NMR. The NMR signals correspond to the anomeric carbons of (a) β -D-fructofuranose, (b) β -D-fructopyranose, (c) β -D-glucopyranose, and (d) sucrose glucosyl C-1 and α -D-glucopyranose. As the hydrolysis of sucrose proceeds, the intensity of the sucrose glucosyl C-1 anomeric carbon signal decreases, while the intensities of the anomeric carbon atoms of the products increase; the pseudo-first-order rate constant for the reaction is $4 \times 10^{-4} \text{ s}^{-1}$. The point of bond cleavage at the fructosyl-(bridge)oxygen bond is observed directly from the ^{18}O isotope shifts: the isotopic composition of the fructose anomers is the same as the solvent upon hydrolysis, while the glucose anomers undergo an oxygen exchange reaction until their isotopic compositions are the same as the solvent. (Reprinted by permission of the American Chemical Society from T. L. Mega and R. L. Van Etten, *J. Am. Chem. Soc.*, 1988, **110**, 6372)

that a significant amount of material may be required for analysis, whereas other techniques require much less material. Nevertheless, studies utilizing ^{18}O isotope shifts have been of major importance in biological NMR.

Any reaction involving carbon-oxygen bonds is potentially amenable to analysis utilizing the ^{18}O isotope shift in ^{13}C NMR. Biological molecules contain many carbon-oxygen bonds, and these bonds are very important sites of reactions. Therefore, it is not unexpected that the ^{18}O isotope shift in ^{13}C NMR has been widespread in biological NMR. These reactions are studied at natural abundance ^{13}C (1.1%), or using ^{13}C -enriched (up to 99 atom %) molecules. A particular experiment will indicate whether the ^{18}O isotopomer(s) should be synthesized, or whether the ^{18}O should be introduced exogenously as $^{18}\text{O}_2$, H_2^{18}O , etc.; both designs are used. The studies can be broadly classified as mechanistic studies and biosynthetic studies. Mechanistic studies include the reactions of enzymes and the reactions of biological molecules in the absence of enzymes. Among the mechanistic studies are oxygen exchange reactions, points of bond cleavage, oxidation reactions, rearrangement reactions, and the source of oxygen in reactions.¹ These studies have provided important information on the reactivity of carbon-oxygen bonds in solution, the bioenergetics and kinetics of reactions under different experimental conditions, the solution (equilibrium) structure of biological molecules, and mechanistic information on enzyme-catalyzed reactions. Figures 3 and 4 illustrate the information available in mechanistic studies. Figure 3 shows the hydrolysis of sucrose in H_2^{18}O at natural abundance ^{13}C NMR.⁹ This is a reaction where the point of bond cleavage at the glucosyl-(bridge)oxygen or at the fructosyl-(bridge)oxygen had remained unresolved, despite intense scrutiny with experimental evidence supporting both proposals. The reaction in Figure 3 shows that the acid-catalyzed reaction proceeds by fructosyl-(bridge)oxygen bond fission, but simultaneously the rates of sucrose hydrolysis and of oxygen exchange reactions of the products could be determined; this long-standing problem was resolved quite elegantly. Figure 4 shows the rat liver microsomal

Figure 4 Homogeneous rat liver microsomal epoxide hydratase (EC 3.3.2.3) catalyzes the hydrolysis of 2,2-dimethyl[3- ^{13}C , ^{18}O]oxirane at the primary carbon-oxygen bond with a pseudo-first-order rate constant of $9.98 \times 10^{-5} \text{ s}^{-1}$ at 35°C . An isotope shift of -0.031 ppm is observed for the primary carbon atom in the ^{13}C -enriched oxirane that is not observed in the ^{13}C -enriched 2-methylpropane-1,2-diol hydrolysis product. (Reprinted by permission of the American Chemical Society from J. M. Risley, F. Kuo, and R. L. Van Etten, *J. Am. Chem. Soc.*, 1983, **105**, 1647)

epoxide hydratase-catalyzed hydrolysis of 2,2-dimethyl[3- ^{13}C , ^{18}O]oxirane.¹⁰ From this reaction it is possible simultaneously to determine that the enzyme catalyzes the hydrolysis of the sterically favored primary carbon-oxygen bond and the rate at which the reaction occurs; by contrast, the acid-catalyzed hydrolysis reaction occurs with fission of the tertiary carbon-oxygen bond.

A significant application of the ^{18}O isotope shift in ^{13}C NMR has been the elucidation of the source/origin of oxygen atoms in biosynthetic studies of natural products.¹ The ^{18}O isotope shift in ^{13}C NMR is a nondestructive technique that permits direct, semiquantitative localization of the ^{18}O label even in highly oxygenated natural products; this technique was a valuable improvement to ascertain the position of the ^{18}O label(s) that had often required circuitous approaches to

resolve. The source of the oxygen in the biosynthesis of natural products may be from ^{18}O -labeled small molecule precursors (such as acetate, propionate, etc.), from $^{18}\text{O}_2$, or from H_2^{18}O . These experiments may be performed at natural abundance ^{13}C or using ^{13}C -enriched molecules. Therefore, there are a number of different approaches to these studies, and, in general, a variety of approaches are taken that involve each of these, which includes the synthesis of ^{13}C -enriched, ^{18}O -labeled precursors. From the labeling pattern obtained for each source of oxygen in a natural product, it is often possible to propose a mechanism (or reduce the number of possible mechanisms) for the synthesis of the natural product. Figure 5 illustrates the use of the ^{18}O isotope shift in ^{13}C NMR to determine the incorporation of oxygen from $^{18}\text{O}_2$ into streptonigrin biosynthesis.¹¹ The natural abundance ^{13}C NMR spectrum shows eight isotope shifts from the incorporation of $^{18}\text{O}_2$ at five sites. These results supported an oxidative β -carboline cleavage mechanism in the biosynthesis of streptonigrin rather than other proposed mechanisms.

Any reaction involving nitrogen–oxygen bonds is potentially amenable to analysis utilizing the ^{18}O isotope shift in ^{15}N NMR. However, biological molecules contain few

nitrogen–oxygen bonds (compared with carbon–oxygen bonds and phosphorus–oxygen bonds), and therefore the ^{18}O isotope shift in ^{15}N NMR has not been used extensively.¹ Because the natural abundance of ^{15}N (0.37%) is very low, ^{15}N -enriched compounds have been used in these studies. All studies have been investigations into the source/origin of oxygen in biosynthetic studies: the oxidation of ammonia to nitrite by *Nitrosomonas europaea* utilizes one oxygen atom from $^{18}\text{O}_2$ and the second oxygen atom from H_2^{18}O ; *Nitrobacter agilis* utilizes H_2^{18}O to oxidize nitrite to nitrate; the oxygen atoms in 3-nitropropanoic acid synthesized by *Penicillium atrovenetum* are from $^{18}\text{O}_2$; and the oxygen atoms in the nitro group of dioxapyrrolomycin produced by *Streptomyces fumanus* are from nitrate.

Any reaction involving phosphorus–oxygen bonds is potentially amenable to analysis utilizing the ^{18}O isotope shift in ^{31}P NMR. Biological molecules contain many phosphorus–oxygen bonds, and by far the most important are phosphate bonds. Thus, the primary focus of studies utilizing the ^{18}O isotope shift in ^{31}P NMR has been on the phosphate bonds in various molecules. In general, the ^{18}O label is incorporated into the phosphate molecule for analysis by

Figure 5 Natural abundance ^{13}C NMR was used to ascertain the incorporation of $^{18}\text{O}_2$ in the biosynthesis of streptonigrin by *Streptomyces flocculus*. The oxygen atoms in streptonigrin derived from O_2 are indicated by an asterisk from the isotope shifts of the specific NMR signals. (Reprinted by permission of the American Chemical Society from W. R. Erickson and S. J. Gould, *J. Am. Chem. Soc.*, 1985, **107**, 5831)

Figure 6 The stereochemical course of isoleucyl-tRNA synthetase-catalyzed activation of isoleucine by ATP was elucidated from the isotopomers of the diastereoisomeric triesters of 3',5'-cAMP (shown at the top; (●) ^{18}O). The ^{31}P NMR spectrum for the equatorial triester is shown on the left and the axial triester is shown on the right. The important ^{31}P NMR signals are the two middle signals for the mono- ^{18}O -isotopomer of each diastereoisomer. The ratios of [$^{16}\text{O}_{\text{ax}}, ^{18}\text{O}_{\text{eq}}$] and [$^{18}\text{O}_{\text{ax}}, ^{16}\text{O}_{\text{eq}}$] indicated a stereochemical mechanism involving inversion of configuration at the P- α atom. (Reprinted by permission of the American Chemical Society from G. Lowe, B. S. Sproat, G. Tansley, and P. M. Collis, *Biochemistry*, 1983, **22**, 1229)

^{31}P NMR (^{31}P is 100% natural abundance), although the use of exogenous H_2^{18}O is possible in some studies. The studies can be generally classified as oxygen exchange reactions, positional isotope exchange, bond cleavage reactions, and stereochemistry studies. These studies have provided important mechanistic information, in particular, for enzyme-catalyzed reactions. Oxygen exchange reactions in inorganic phosphate proceed sequentially with exchange of one oxygen atom per event, or with multiple exchange of more than one oxygen per event. Positional isotope exchange occurs in a reversible reaction that involves rotational symmetry of a chemical group where the position of an isotope is exchanged by rotation within a substrate; among these reactions are the reversible $\gamma\text{-PO}_3$ transfer in ATP reactions by different enzymes. The sites of phosphorus–oxygen bond fission have been ascertained in bond cleavage reaction studies. The stereochemical course of phosphate transfer can occur with retention of configuration or with inversion of configuration. These reactions require the synthesis of a chiral substrate, such as a [$^{16}\text{O}, ^{17}\text{O}, ^{18}\text{O}$]phospho or [^{18}O]phosphothio substrate. Analysis of the stereochemical course of these reactions involves the stereospecific cyclization of a chiral phosphate monoester of a chiral diol into a cyclic phosphate diester, esterification of the diester to give

diastereoisomeric cyclic phosphate triesters, and determining the ratios of the [$^{16}\text{O}_{\text{ax}}, ^{18}\text{O}_{\text{eq}}$] and [$^{18}\text{O}_{\text{ax}}, ^{16}\text{O}_{\text{eq}}$] axial and equatorial triesters. Figure 6 shows the ^{31}P NMR spectrum for the stereochemical course of isoleucyl-tRNA synthetase-catalyzed activation of [$^{18}\text{O}_2$]isoleucine by adenosine 5'-[(*R*)- α - ^{17}O]triphosphate.¹² Analysis of the diastereoisomeric triesters of the isolated [$^{16}\text{O}, ^{17}\text{O}, ^{18}\text{O}$]AMP showed inversion of configuration at the α phosphorus atom, which supported a direct in-line displacement of pyrophosphate from P- α of ATP by isoleucine rather than a double-displacement mechanism involving an adenylyl–enzyme intermediate.

1 INTRODUCTION

The basic pancreatic trypsin inhibitor (BPTI) from bovine pancreas¹ has a molecular weight of 6500 and consists of 58 amino acid residues. The amino acid sequence and the molecular conformation in single crystals² are known, and it has been found that the solution conformation of BPTI is unusually stable towards denaturing agents and heat. Some time ago we briefly discussed proton NMR data which revealed yet another rather unexpected structural feature of BPTI, i.e. very slow exchange of some of the amide protons.³ This paper presents new data on the denaturation of BPTI and the proton exchange in solutions of BPTI in D₂O. An obvious goal of the investigations of BPTI is to understand in more detail the mode of action of this inhibitor. In addition, since BPTI is by its small size amenable to detailed studies by different techniques, work on this molecule could on a more general basis be particularly valuable for the further development of the investigations of molecular conformations in proteins. In view of the temperature stability of BPTI, some of the data on this protein might conceivably even be relevant for the investigation of conformational features in proteins from thermophilic organisms.

This quotation represents the introduction of the first paper from my laboratory that was devoted entirely to BPTI.⁴ We started work on this protein in 1972, and at the time no one could have guessed that I would some day be asked to write an article on BPTI for the *Encyclopedia of Nuclear Magnetic Resonance*. However, the prediction made lightheartedly in 1973, that work with BPTI might be 'particularly valuable' for the future development of research on protein structures, turned out to have been, if anything, an understatement. In the meantime my laboratory has published more than 70 papers on experiments with BPTI and 15 papers on work with chemical modifications and homologs of BPTI, and by now the output of NMR papers on BPTI by other groups exceeds these numbers by far. Outside of the NMR field, BPTI was

one of the first proteins, in 1975, for which a refined high-resolution X-ray crystal structure became available,⁵ which in turn made BPTI a preferred object for theoretical studies on protein structure and dynamics.⁶ At that time BPTI was also already used for studies on protein folding.⁷ In 1982, BPTI was the first protein for which the ¹H NMR spectrum was completely assigned,⁸ which contributed greatly to making it a focal point for research on amide proton exchange in proteins.⁹ More recently, numerous projects on protein-folding studies and amide proton exchange measurements with BPTI relied heavily on the use of NMR for characterization of molecular structures and for kinetic measurements. For the sake of completeness it should also be added that a vast body of literature on the biochemistry and physiology of BPTI provides the platform for the physicochemical and structural investigations.

Figure 1 presents a ribbon drawing of the polypeptide backbone fold in BPTI, and a stereo view of the complete NMR solution structure¹⁰ is shown in Figure 2. The polypeptide backbone forms a 3₁₀-helix from residues 3 to 7, a β -hairpin of residues 18–35, a one-residue third antiparallel β -strand of residue 44, and an α -helix of residues 47–56. There are three disulfide bonds linking the cysteinyl residues 5–55, 14–38, and 30–51. The molecule contains four phenylalanyl residues in positions 4, 22, 23, and 45, and the four tyrosyl residues 10, 21, 23, and 35 as the only aromatic side chains. The arrangement of the polypeptide backbone and the interior side chains (green and blue in Figure 2) is nearly identical in crystals⁵ and in solution.¹⁰ The conformation of the protein surface (red in

Figure 1 Ribbon drawing of the three-dimensional NMR solution structure of BPTI.¹⁰ The three disulfide bonds 5–55, 14–38, and 30–51 are displayed as solid lines tracing the covalently linked side chains. For easy reference some residue positions have been identified. (Drawing prepared using the atom coordinates from Berndt et al.¹⁰)

Figure 2 Stereo view of the NMR solution structure of BPTI represented as a superposition of 20 conformers. All heavy atoms are displayed. Color code: green, polypeptide backbone; blue, core side chains; red, surface side chains. A close fit among the 20 conformers indicates regions of the molecule where the structure is well defined, whereas a large dispersion implicates the presence of (dynamically) disordered structure. (Drawing prepared using the atom coordinates from Berndt et al.¹⁰)

Figure 2) and the surface hydration¹¹ in solution are highly dynamic and different from the X-ray structure because of crystal lattice effects. The globular structure of BPTI is stable over the pH range 2–10 at ambient temperature, and over the temperature range 1–90 °C at neutral pH. Physicochemical studies of the folded protein can thus be performed with extensive variation of the experimental conditions.

2 GROWING UP WITH BPTI

Considering the long years of our involvement with BPTI, it is inevitable that this account has a personal note. There is only one other protein that influenced the activities of my group in a comparable way, i.e. cytochrome *c* (see *Wüthrich, Kurt: NMR Structures of Biological Macromolecules*). However, it was with BPTI that we were introduced to protein structures and the physical chemistry of proteins. When dealing with cytochrome *c* our interest was focused on the one hand on NMR experimentation, and on the other hand on the heme group and its immediate surroundings. For example, all our theoretical work connected with cytochrome *c* and other hemoproteins related to ligand field treatments of the electronic states of the heme iron. With BPTI we became motivated to understand protein structure at a more general level, and through frequent contacts with Robert Huber's group in Munich we also learned about protein crystallography. In particular, during the first 3 years of our NMR work, when we mostly tried to rationalize NMR spectral properties on the basis of the BPTI crystal structure, Deisenhofer and Steigemann⁵ refined the original BPTI structure at 0.15 nm resolution, and we got access to the improvements from the original molecular

model² to the final refined structure in several steps. At that time, the X-ray data were visualized by physical molecular models, and the coordinates were obtained by measuring interatomic distances in these models. I remember a day when local structural features contained in a preliminary set of atom coordinates provided by the Munich group completely upset some calculations in my laboratory. A trip to Munich then revealed that there had been an impact on the BPTI model by an unidentified object (probably a broomstick in the hands of the cleaning personnel) before the atom coordinates were measured. Unimportant as this story is in perspective, it was the kind of experience we needed to develop a realistic view of experimental protein structure determination.

As happens so often with timely research projects, we were not alone in 1973 in starting publishing NMR work with BPTI. Brian Sykes and his co-workers reported studies of the amide protons and the tyrosyl rings,¹² and pursued the investigations of the tyrosyls with the use of chemical modification.¹³ We thus had an opportunity to practice functioning under the pressure of direct competition. Starting around 1975, more and more theoretical work appeared that related directly to our experimental data,⁶ which gave us good motivation to get more thoroughly educated in this area.

3 SURVEY OF KEY NMR EXPERIMENTS WITH BPTI

In Table 1 I have identified 19 key events which have been directly associated with BPTI during the period from the initial NMR experiments with BPTI in 1972^{3,4,12} until the completion of the first NMR structure determination of a protein in

Table 1 Key NMR Experiments with BPTI, 1973–84

Year	Experiment/Observation	Ref.
1973	¹ H NMR of individual amide protons	4, 12
1974	Ring flips of Phe and Tyr	14
1975	Theory of ring flips	6, 15

1983	Phase sensitive 2QF-COSY	33
1984	Structure calculation from NMR data using the program DISGEO	34

1984.³⁵ These were either developments of new NMR experiments, important steps toward protein structure determination from NMR data, or NMR observations relating to novel features of protein conformation, and they will be discussed in more detail in the following sections. The selection is based on general considerations of the follow-up activities as reflected, for example, in the citation record, but also on my memory of the impact from these events on our subsequent projects. Table 1 contains mostly references to our own work, since besides several papers on amide proton exchange, mostly by Clare Woodward's group,^{19,22} only seven NMR studies with BPTI were published by others up to 1984. These are four papers by Brian Sykes's group,¹² of which three are on nitrotyrosyl derivatives of BPTI,¹³ two are on refolding of heat-denatured, modified BPTI,³⁶ and a theoretical paper is on chemical shift averaging.³⁷ In addition, by 1984 BPTI was more and more widely used as a standard to check instrument performance.

In recent years in my laboratory, BPTI has lost its pivotal role of the 'heroic era' up to 1984, but elsewhere applications of NMR techniques became more and more widespread in projects on the folding, stability, and dynamics of BPTI (see Section 10 below).

4 BPTI AND NMR SPECTROSCOPY WITH PROTEINS

In the 1970s my group worked mainly with hemoproteins, oligopeptides, and BPTI (see *Wüthrich, Kurt: NMR Structures of Biological Macromolecules*). Among the proteins studied, BPTI was the most robust (see above), and it could be dissolved in water at concentrations up to 20 mM. It is not surprising, therefore, that it was used for most of the NMR technique developments in my laboratory. The first such entry

in Table 1 is the sine-bell,¹⁶ which was of particular practical importance during all those years when absolute value presentations of the 2D NMR spectra were used.^{8,17,24–29} It continues to be widely applied, and is a fitting tribute to the beautiful spectroscopy performed by the late Antonio DeMarco during his all too short life span.

The remaining technique entries refer to early 2D NMR experiments. 2D *J*-resolved spectroscopy had previously been developed in Richard Ernst's laboratory, but the BPTI paper in 1977¹⁷ presents not only the first 2D NMR spectrum of a protein, but also the first 2D spectra recorded with a data size that made the technique useful for practical applications beyond observation of the classical test compounds, such as CH₃I or CH₃CH₂OH. SECSY²⁴ was designed as an alternative to the previously described COSY scheme to overcome limitations imposed by the then available computer capacities. For several years, until phase sensitive 2D NMR became available as a daily routine,^{38,39} the concept of delayed acquisition used in SECSY was widely propagated also by the instrument manufacturers. From our 1D experiments with BPTI²¹ (see also the following section) and cytochrome *c*^{40,41} it was clear in 1978 that NOEs would be the key parameter for studies of macromolecular structures. The first 2D NOESY spectrum on record²⁵ was obtained with BPTI by Anil Kumar in my laboratory during the Christmas recess of 1979. Funding for this project was obtained through a grant application submitted jointly with Richard Ernst in 1978, which requested support for developing improved NOE measurements, including 2D NOESY. Within weeks after the first successful NOESY experiment we recorded homonuclear 2D NMR spectra in H₂O solutions of proteins.²⁶ This was an important step ahead, which enabled the extension of the NMR assignments in the protein core, where the amide protons exchange sufficiently slowly to be observed in D₂O, to the molecular surface. Although the preirradiation used to suppress the solvent line lacks the sophistication of other solvent suppression schemes, it turned out to be exactly what was needed for complete protein structure determinations by NMR. A further fundamentally important advance was to repeat the earlier 1D NMR measurements of NOE build-up curves for BPTI using 2D NOESY.²⁹ BPTI was also used in the first application of a two quantum filter for further improvement of the high-resolution phase sensitive COSY spectra of proteins³³ which we had obtained with the earlier implementation of time proportional phase incrementation (TPPI) by Dominique Marion.³⁸

5 BPTI AND RESONANCE ASSIGNMENTS IN PROTEINS

In 1975, initial resonance assignments in BPTI were obtained for the aromatic region by Brian Sykes's group using chemical derivation of the tyrosyl rings¹³ and in my laboratory using spectroscopic techniques.⁴² In the following years we tried just about any available approach to add assignments for other amino acid side chains in BPTI,⁴³ but the decisive breakthrough that opened the way to NMR structure determination of proteins^{44,45} came in 1978 with the successful 'sequential NOE walk' by Andreas Dubs and Gerhard Wagner for obtaining sequential assignments of the

Figure 3 Stacked-plot representation of a symmetrized, absolute-value 500 MHz ^1H COSY spectrum of a 0.02 M solution of BPTI in a mixed solvent of 90% H_2O and 10% D_2O , pH = 4.6. $T = 80^\circ\text{C}$. The spectrum was recorded in ~ 24 h. The digital resolution is 5.3 Hz/point. Due to the symmetrization the residual perturbations from the water suppression appear as a band of weak peaks parallel to the diagonal. (Reproduced with permission from G. Wagner and K. Wüthrich, *J. Mol. Biol.*, 1982, 155, 347)

β -sheet in BPTI (see Figure 1).²¹ This approach was based on detailed inspection of the BPTI crystal structure (see the following section) and on NMR techniques used previously in our laboratory for a similar sequential walk around the heme group in hemoproteins.⁴⁰ Once the aforementioned 2D NMR experiments were available, the assignments could be extended to other regions of BPTI,^{27,28} and when we obtained a 500 MHz spectrometer in 1981 the complete polypeptide chain in BPTI was assigned.⁸ Figure 3 shows a COSY spectrum from the assignment paper,⁸ illustrating Gerhard Wagner's mastery of the art of NMR spectroscopy with proteins. Over the years this figure has appeared more than 10 times on the cover of books and journals, and a decade after its original publication I was quite surprised to find it also on the EENC poster.

6 BPTI AND PROTEIN STRUCTURE DETERMINATION BY NMR

From joint inspection of NMR data and the high-resolution X-ray crystal structure of BPTI, which was started in a systematic way by Andreas Dubs and Gerhard Wagner in connection with the initial sequential assignment,²¹ we obtained important insights which resulted in a theoretical basis for the sequential resonance assignment technique⁴⁶ and a pattern recognition approach for the identification of secondary structures in proteins.^{47,48} The crucial BPTI contribution to structure calculation from NMR data, however, was the paper with Timothy Havel listed as the last entry in Table 1.³⁴ Using the program DISGEO and simulated input data sets of NOE upper-distance constraints derived from the BPTI crystal structure, this paper demonstrated that complete protein structures at atomic resolution could indeed be obtained from experimental NMR data, and by extensive controlled variation of the simulated input it could also be shown that the method would be robust with respect to incomplete collection

of input data as well as low precision of the individual NOE distance measurements.

Considering the extent to which our activities in the early 1980s were focused on BPTI, the questions must arise why even in 1987 only a low-resolution NMR structure had been published,⁴⁹ and why a complete high-quality structure determination was achieved only in 1992.⁵⁰ An initial BPTI structure calculation from NMR data had indeed already been performed in 1982 by Werner Braun and Gerhard Wagner (unpublished). The software used was an implementation of a metric matrix distance geometry algorithm that had the capacity of handling all-atom structures of oligopeptides with up to about 10 amino acid residues, which had been used successfully for a structure determination of the nonglobular polypeptide hormone glucagon.^{51,52} For the calculations with BPTI a simplified presentation of the polypeptide chain had to be adopted, with each amino acid residue described by two spheres representing the backbone and the side chain, respectively. The fit of the resulting structure with the X-ray crystal structure⁵ was not significantly better than that of model calculations done at the same time by others without use of experimental data. I accepted this outcome as a clear-cut documentation that protein structure calculations from NMR data have to be performed with the complete covalent polypeptide structure to represent properly both the van der Waals constraints and the chirality of the individual residues. We also realized, from comparison with other proteins as well as with simulated input data from the BPTI crystal structure, that we were not obtaining a good quality input of conformational NMR constraints for BPTI. Eventually it turned out that the generally available BPTI preparations contain about 10% of closely related BPTI analogs. Although this did not interfere either with the use of BPTI for the development of NMR techniques or with the resonance assignments, it made the collection of an extensive set of NOE distance constraints as input for a structure determination difficult, since the assignments of many NOESY cross peaks remained ambiguous. Furthermore, work with a recombinant isotope-labeled mutant BPTI also confirmed earlier observations by Gerhard Wagner that some resonance lines were not observed because of conformational exchange, which was now traced to a dynamic equilibrium between the two different chiral forms of the disulfide bridge 14–38 (see Figure 1).⁵³ Based on this information and with the use of a homogeneous protein sample, a high-quality structure determination was finally obtained in 1992.⁵⁰

7 BPTI AND AMIDE PROTON EXCHANGE

Figure 4 shows the first BPTI spectrum published by my laboratory in 1973^{3,4} (comparison with Figure 3 affords a good illustration of the progress made during the following decade), and the high-frequency region illustrates part of an early amide proton exchange measurement. The protein was dissolved in D_2O , and the replacement of individual amide protons by deuterons was followed by measurement of the decrease of the intensities of the corresponding resonance lines with time. In Figure 4, the loss of intensity between the two spectra recorded within 10 min and 170 h after sample preparation, respectively, is readily apparent. This was one of the few experiments with proteins that could be done well in 1973 (see *Wüthrich, Kurt:*

Figure 4 Proton NMR spectrum at 220 MHz of a 0.01 M solution of BPTI in D₂O, pD = 7.7, $T = 20^{\circ}\text{C}$. Two spectra were recorded 170 h (a) and 10 min (b) after the preparation of the solution. (Reproduced with permission from A. Masson and K. Wüthrich, *FEBS Lett.*, 1973, **31**, 114)

NMR Structures of Biological Macromolecules), and so we started to collect exchange data with BPTI under a wide variety of conditions of pH, temperature, and ionic strength, and subsequently also with homologs and chemical modifications of BPTI.

Amide proton exchange measurement has been a classical approach in protein chemistry long before any such studies were started with BPTI, dating back to the days of the Linderstrøm–Lang laboratory in Copenhagen.⁵⁴ The NMR measurements with BPTI added a new element in that the exchange from individual sites in the protein could be followed, whereas earlier techniques yielded information only on the percentage of the ensemble of all amide protons that had exchanged after a certain time span.⁵⁴ The new potentialities of NMR were soon recognized by those specializing in the field of amide proton exchange,⁵⁵ and in particular Clare Woodward and her group^{19,22} started to perform NMR exchange measurements with BPTI under a wide range of conditions. The follow-up to the NMR studies on amide proton exchange listed in Table 1^{18–20} continues to the present, and the mechanisms for amide proton exchange in BPTI proposed in 1979^{22,23} provide a much discussed background.

The next advance came with the individual assignments of amide proton NMR lines,²¹ so that exchange rates could be attributed to unique sites in the BPTI crystal structure.^{20,23} This step was completed in 1982, when a map of all individual exchange rates in BPTI was obtained.⁵⁶ The last entry on this topic in Table 1^{30,31} covers experiments by Heinrich Roder in which experimental conditions were identified where the exchange in a chemically modified BPTI derivative proceeds via a so-called EX₁ process, so that the exchange rates are directly related to the frequencies of protein structure fluctuations.⁵⁴ This paper shows that EX₁ processes for amide proton exchange in proteins can be obtained only under extreme conditions which are not normally used for exchange measurements. Therefore, nearly all available exchange data are governed by EX₂ processes, where the exchange rates are not directly related to the frequencies of internal motions in the protein structure but rather to the acid/base-catalyzed reaction at the amide group modulated by conformational equilibria in the protein.²³

8 BPTI AND INTERNAL MOBILITY IN PROTEINS

In the X-ray crystal structure of BPTI the aromatic rings of phenylalanine and tyrosine are among the side chains with the smallest temperature factors.⁵ For each ring the relative values of the *B*-factors increase toward the periphery, so that the largest positional uncertainty is indicated for the C-4 position on the symmetry axis through the C β –C γ bond. The observation of ring-flipping motions on the millisecond to microsecond timescale (Figure 5)¹⁴ was therefore a genuine surprise, since it appeared to be incompatible with the crystal structure. Theoretical studies performed in a collaboration of my group with Robert Huber's laboratory,¹⁵ and independently by Martin Karplus's group⁶ then showed that the crystallographic *B*-factors sample multiple rotation states about the C α –C β bond, whereas the ring flips about the C β –C γ bond seen by NMR are very rapid 180° rotations connecting two indistinguishable equilibrium orientations of the ring. The *B*-factors do not manifest these rotational motions because the populations of all nonequilibrium rotational states about the C β –C γ bond are vanishingly small. The ring flip phenomenon, which turned out to be a general feature of globular proteins, thus showed that there are low-frequency internal motions in protein molecules, which have activation energies of 60–100 kJ mol^{–1} and amplitudes of $\gtrsim 0.1$ nm, and involve concerted displacements of numerous groups of atoms. Ring flips have since been the subject of a long series of theoretical and experimental investigations.

Working with a series of chemical modifications of BPTI and homologous proteins, we observed in 1978¹⁸ that amide proton exchange rates measured under conditions of EX₂ exchange are correlated with the thermal stability of the protein, i.e. corresponding protons would exchange more rapidly in the less stable proteins. In contrast, the ring flip rates, which are directly related to the frequencies of internal protein structure fluctuations, were found to be insensitive to protein stability as long as the 3D structure was preserved at the conditions of the experiment.

BPTI continues to be a source of observations on dynamic features which turn out to be common to globular proteins at large. Most important, it was with BPTI that we succeeded in 1989 in observing individual molecules of hydration water by NMR,⁵⁷ to demonstrate that internal hydration water molecules exchange with the bulk solvent on a millisecond timescale or faster,⁵⁸ and to distinguish qualitatively between interior hydration sites and surface hydration,¹¹ which provides a rationale for the generally observed dynamic surface disorder in NMR solution structures of globular proteins (see Figure 2). Another novel dynamic feature identified recently in BPTI is the aforementioned slow interconversion between two conformation states of the disulfide bond 14–38,⁵³ which was also clearly manifested in ¹⁵N $T_{1\rho}$ measurements.⁵⁹

9 BPTI AND PROTEIN FOLDING

One of the 1981 entries in Table 1 is the amide proton trap experiment for studies of early events in protein refolding, which was performed as part of Heinrich Roder's Ph.D. thesis in 1981.^{30,32} This experiment and refined forms thereof became very popular in the late 1980s, and it is now one of

Figure 5 1D 360 MHz ^1H NMR spectra at variable temperature of a 0.01 M solution of BPTI in D_2O , $\text{pD} = 7.8$. The region from 6.0 to 8.5 ppm is shown. The resonances of the aromatic rings of Phe-45 (○) and Tyr-35 (▲) were simulated in the center and on the right, respectively, using the ring flip frequencies indicated with the individual spectra. The resonance assignments in the simulated spectra refer to the standard numeration for the aromatic rings of phenylalanine and tyrosine. (Reproduced by permission of Wiley from K. Wüthrich, 'NMR of Proteins and Nucleic Acids', 1986)

the standard techniques in laboratories working on the protein-folding problem.

As mentioned in the introduction, BPTI has long played an important role in the area of protein folding,⁷ and early attempts to use NMR experiments for folding studies have already been cited.^{32,36} More recently, NMR has been used extensively for structural characterization of BPTI folding intermediates containing only part of the native disulfide bonds (see Figure 1), mainly in the laboratories of Thomas Creighton⁶⁰ and Peter Kim.⁶¹

10 CONCLUDING REMARKS

BPTI has been a focal point for my research group from 1973 until about 1984, when our main activities shifted away from method development toward applications of NMR for protein structure determination in a variety of different systems. This article covers mainly the period of our intense involvement with this protein. Around 1985 we undoubtedly had a feeling of saturation with BPTI, which was also nurtured

by referee comments on 'yet another paper on BPTI'. Things were rather quiet for several years after 1985, but in the late 1980s research with BPTI picked up momentum again, triggered primarily by the production of recombinant mutants of BPTI and the possibility of labeling the recombinant proteins with isotopes. Although crystal structures of at least 10 BPTI mutants have been described during the last few years, most of the structural work is done using NMR in connection with folding studies.^{60,61} These were recently very much in the limelight due to a widely publicized controversy between Thomas Creighton and Peter Kim on certain aspects of the BPTI refolding pathway. Listening to a presentation by Clare Woodward at the 1994 Annual Meeting of the US Biophysical Society I also learned that the correlation between thermal stability of the folded protein and amide proton exchange rates^{18,23} is being further investigated with the use of recombinant BPTI mutants. Overall, considering the advanced techniques now available for protein preparation and NMR investigations, we can look forward to many more years of excitement in research with BPTI.

1 INTRODUCTION

Peptides and proteins carry out an immense variety of biological functions. In order to perform these roles, the polypeptide molecules adopt well-defined three-dimensional structures. Despite the fact that the number of possible combinations of backbone torsion angles for a given polypeptide chain is essentially infinite, a large percentage of the residues in a protein are usually found in standard elements of secondary structure such as β -turns, α -helices, and β -sheets. Thus, determination of the secondary structure of a protein is a major step towards elucidating its global tertiary fold. The same elements of secondary structure are also found commonly in the bioactive conformations of naturally occurring peptides, and identification of such elements is crucial if bioactive conformations are to be defined.

NMR spectroscopy is the most powerful technique for analyzing in detail the secondary structure of peptides and proteins in solution. Pioneering work by Wüthrich and co-workers^{1,2} showed that elements of secondary structure in polypeptides could be easily identified from observed NOE patterns, since each type of secondary structure is characterized by a different set of short interproton distances. This is illustrated in Figure 1, where the most common types of secondary structure (type I and II β -turns, α -helix, and antiparallel and parallel β -sheet) are represented, and the most characteristic, close interproton interactions for each type of structure are indicated by arrows. The relevant interproton distances and standard backbone torsion angles are listed in Table 1. In addition to NOE patterns, other NMR parameters such as coupling constants, chemical shifts, amide temperature coefficients, and amide H/D exchange rates, can also be used to define the secondary structure of polypeptides.

In this article we illustrate how information obtained by NMR spectroscopy techniques in solution can be used to analyze the presence of β -turns, α -helices, and β -sheets in peptides and proteins, and we discuss particular facets associated with the identification of each type of secondary structure. Examples from both the peptide and the protein NMR literature will be used. Although the principles involved in the conformational analysis of peptides and proteins by

Figure 1 Characteristic short interproton distances in β -turns, α -helices, and β -sheets. Dashed lines indicate hydrogen bonds and curved arrows indicate the characteristic interproton distances (only one example of each interaction is indicated). The values of the interproton distances are shown in Table 1. The following types of secondary structure and corresponding interproton distances are shown: (a) type I β -turn, $d_{NN}(i+1, i+2)$, $d_{NN}(i+2, i+3)$, $d_{\alpha N}(i+1, i+3)$; (b) type II β -turn, $d_{\alpha N}(i+1, i+2)$, $d_{NN}(i+2, i+3)$, $d_{\alpha N}(i+1, i+3)$; (c) α -helix, $d_{NN}(i, i+1)$, $d_{\alpha N}(i, i+3)$, $d_{\alpha N}(i, i+4)$, $d_{\alpha N}(i, i+5)$; (d) antiparallel β -sheet, $d_{\alpha N}(i, i+1)$, $d_{\alpha N}(i, j)$, $d_{\alpha N}(i, j+1)$, $d_{NN}(i, j)$; (e) parallel β -sheet, $d_{\alpha N}(i, i+1)$, $d_{\alpha N}(i, j)$, $d_{NN}(i, j)$

NMR are the same, some differences exist in the methodology used, both because of diversity in the goals pursued and because of general distinctions in structural and dynamic characteristics.

Naturally occurring peptides are usually unstructured in solution and only adopt a specific conformation(s) when they perform their function, for instance upon interaction with a receptor. Direct observation of the bioactive conformation is usually hindered because most receptors are membrane bound proteins. Thus, much of the research on conformational analysis of biologically active peptides has concentrated on analogs incorporating constraints that limit their conformational degrees of freedom and favor adoption of their bioactive conformations.³ A large body of work on peptide conformation has also been directed to peptides as models of protein substructures,³ with the goal of understanding the preferences of individual amino acid residues for different types of secondary structure. The model peptides often contain constraints and are designed with specific amino acid sequences to favor a particular type of structure. Analysis of peptides is often performed in the presence of organic solvents such as deuterated 2,2,2-trifluoroethanol (TFE), which induce the formation of secondary structure. Even with the aid of constraints and

2 PEPTIDE AND PROTEIN SECONDARY STRUCTURAL ELEMENTS

Table 1 Characteristic Short Interproton Distances (nm) and Standard Backbone Torsion Angles in β -Turns, α -Helices and β -Sheets^a

	Type I β -turn			Type II β -turn		α -Helix	Antiparallel β -sheet	Parallel β -sheet
Torsion angles (deg.)								
ϕ	−60	−90	−60		80	−57	−139	−119
ψ	−30	0	120		0	−47	135	113
Interproton distances (nm)								
$d_{\alpha N}(i,i+1)$	0.35	3.2	0.21	0.32	0.32	0.35	0.21	0.21
$d_{\alpha N}(i,i+2)$	0.36		0.32			0.45		
$d_{\alpha N}(i,i+3)$		0.32–0.44		0.38–0.48		0.35		
$d_{\alpha N}(i,i+4)$						0.41		
$d_{NN}(i,i+1)$	0.26	0.24	0.46		0.25	0.27	0.44	0.43
$d_{NN}(i,i+2)$	0.39		0.42			0.42		
$d_{\beta N}(i,i+1)$	0.29–0.43	0.36–0.46	0.36–0.46		0.36–0.46	0.25–0.40	0.32–0.44	0.37–0.46
$d_{\alpha\beta}(i,i+3)$						0.26–0.44		
$d_{\alpha\alpha}(i,j)$							0.23	0.47
$d_{\alpha N}(i,j)$							0.31	0.30
$d_{NN}(i,j)$							0.33	0.39

^aThe interproton distances were measured on model alanine-based peptides using the program INSIGHT (Biosym Technologies Inc.). The most characteristic NOE interactions are indicated in 1 by curved arrows. In the α -helix and β -sheet, residue i corresponds to an arbitrary residue in the sequence. In the β -sheet, residue j corresponds to a residue apposed to residue i in a contiguous strand. The four residues in a β -turn are numbered i to $i + 3$. Torsion angles correspond to residues $i + 1$ (left) and $i + 2$ (right). The $d(i, i + 1)$ distances indicated refer to $d(i + 1, i + 2)$ (left) and $d(i + 2, i + 3)$ (right), while $d(i, i + 2)$ refers to $d(i + 1, i + 3)$.

structure-inducing solvents, it is paramount to consider the possibility of conformational averaging in any study of peptide conformation. Conformational analysis of peptides is also hindered by the fact that most protons are in the periphery of the molecule and thus only a small number of NOEs per residue can be measured. However, measurement of interproton distances can usually be accomplished with higher accuracy for peptides than for proteins, due to higher simplicity of the spectra, longer relaxation times, and less spin diffusion.

Proteins usually have well-defined structures, and conformational averaging occurs only in flexible turns or loops. Although the measurement of accurate interproton distances is hindered by spin diffusion, the existence of a large number of NOE interactions per residue facilitates the determination of high resolution structures. The emphasis in protein structure determination^{2,4,5} is generally on analyzing native structures with the highest detail possible, understanding interactions with ligands, and determining conformational changes associated with the execution of their biological roles. However, there is increasing interest in the analysis of denatured states of proteins,⁶ which are important to protein folding and have higher flexibility than the native states.

2 β -TURNS

β -Turns are sites where the polypeptide chain reverses its overall direction, allowing proteins to adopt a globular shape (for a review see Rose et al.⁷). Because of their surface location and because they facilitate side-chain exposure, β -turns provide ideal sites for molecular recognition. Thus, β -turns also occur very often in the bioactive conformations of naturally occurring peptides. β -Turns comprise four amino acid residues (usually numbered i to $i + 3$), and the different types of β -turn are distinguished by the backbone torsion

angles of the central residues ($i + 1$ and $i + 2$). Type I and II β -turns (see Figure 1 and Table 1) are the ones most commonly found in proteins.⁸ Their mirror images, type I' and II' β -turns, are less common and have a tendency to appear in β -hairpins.

The interproton distances characteristic of type I and type II β -turns are similar, with the exception of those between the amide proton of residue $i + 2$ and the H- α and HN protons of residue $i + 1$ (Table 1). The NMR parameter that is most characteristic of β -turns is the strong NOE between the amide protons of residues $i + 2$ and $i + 3$. Type II β -turns are easily identified because of the absence of other d_{NN} NOEs and the presence of a strong $d_{\alpha N}(i + 1, i + 2)$ interaction. In contrast, in type I β -turns the $d_{\alpha N}(i + 1, i + 2)$ NOE is weak, and there is usually a $d_{NN}(i + 1, i + 2)$ NOE. Thus, the sequential NOE patterns associated with type I β -turns are similar to those of an α -helix. Type I β -turns can be distinguished from α -helices because of the presence of a $d_{\alpha N}(i + 1, i + 3)$ NOE (also characteristic of type II β -turns) and the absence of a repetitive pattern of d_{NN} , $d(i, i + 3)$, and $d(i, i + 4)$ interactions. In both type I and type II β -turns the amide protons of the corner residues ($i + 1$ and $i + 2$) are exposed to the solvent, while the amide proton of residue $i + 3$ is usually hydrogen bonded with the carbonyl group of residue i ; thus, the latter amide proton usually has decreased H/D exchange rate and its chemical shift has a low temperature coefficient.

Although the formation of stable secondary structure in linear peptides is unusual, several cases of linear peptides adopting substantial populations of β -turn conformations have been described. Particularly interesting is the finding of a significant population of a β -turn conformation in the first four residues of the pentapeptide Tyr-Pro-Tyr-Asp-Val,⁹ corresponding to the immunodominant region of a larger peptide derived from influenza virus hemagglutinin. The turn conformation was mainly deduced from the presence of $d_{NN}(3,4)$ and $d_{\alpha N}(2,4)$ NOEs, and from the low temperature

coefficient of the Asp⁴ HN. The temperature coefficient of Asp⁴ HN in a series of analogous peptides, where Tyr³ was replaced by other residues, was used as a measure of the β -turn populations in the peptides, and these populations correlated with β -turn probabilities calculated from protein crystal structures.

NMR studies on the propensities of amino acid residues to occur in different positions of β -turns have been more commonly performed using constrained peptide models,^{3,7,10} in particular cyclic peptides. These studies have shown, for instance, that proline residues have a high tendency to occur in the $i + 1$ position of both type I and type II β -turns, and that glycine has a preference for the $i + 2$ position of type II β -turns and for the $i + 1$ position of type II' β -turns, in good correlation with the preferences observed in proteins. The positions preferred by Gly residues are characterized by torsion angles corresponding to regions of the Ramachandran map that are energetically unfavorable for L-amino acids, but not for D-amino acids. Indeed, replacement of Gly residues by D-amino acids stabilizes the turn conformations, and L-Xaa-D-Yaa and D-Xaa-L-Yaa dyads have a high tendency to be in the corner positions of type II and type II' β -turns, respectively. Observations such as the above have been used in peptide analog design to stabilize turn conformations hypothesized to be important for biological activity in naturally occurring peptides. An example is gonadotropin releasing hormone (GnRH), whose bioactive conformation was proposed to contain a type II' β -turn around the residues Gly⁶-Leu⁷. A series of highly potent, constrained GnRH antagonists containing a covalent bridge between residues 4 and 10, and D-amino acids in position 6, was designed. Analysis by NMR of one of these compounds¹¹ showed that it adopts the predicted type II' β -turn conformation, as evidenced by the observation of a very low temperature coefficient for the amide proton of residue 8, and of the following interproton distances: $d_{\alpha N}(6,7) = 0.22$ nm, $d_{\alpha N}(7,8) = 0.31$ nm, and $d_{NN}(7,8) = 0.25$ nm (note that in this case the interproton distances corresponding to a type II' β -turn are the same as in a type II β -turn, described in Table 1). This example also illustrates the high accuracy that can be achieved in the measurement of interproton distances for small peptides.

NMR studies of cyclic pentapeptides have provided a good example of conformational averaging between a discrete number of conformations involving β -turns.¹² NMR data obtained for cyclo(Gly-Pro-D-Ala-Gly-Asn), cyclo(D-Ala-Pro-Asn-Gly-Pro), and cyclo(Gly-Pro-Ala-D-Phe-Pro) showed that the three peptides adopt β -turn conformations with Pro² H- α and the HN in position 3 for the three peptides, obtained from one-dimensional NOE difference spectra, are shown in Figure 2. The distance measured for the Pro-D-Ala peptide (0.20 nm) is consistent with the presence of a type II β -turn, which is favored by the LD sequence. However, the distances observed for the Pro-Asn and Pro-Ala peptides were 0.245 and 0.29 nm, respectively, which are intermediate between those expected for type I (0.35 nm) and type II (0.21 nm) β -turns (Table 1). Other measured interproton distances and molecular dynamics simulations supported the conclusion that these two peptides exist in an equilibrium between type I and type II β -turn conformations (fast on the NMR timescale), rather than adopting an intermediate conformation between the two

Figure 2 NOE buildup curves obtained from the integrated intensities of Pro² H- α resonances, after saturation of the HN signal of residue 3, in one-dimensional NOE difference spectra of: (Δ) cyclo(Gly-Pro-D-Ala-Gly-Asn), (◇) cyclo(D-Ala-Pro-Asn-Gly-Pro), and (□) cyclo(Gly-Pro-Ala-D-Phe-Pro). (Reproduced by permission of John Wiley & Sons, Inc., from S. J. Stradley, J. Rizo, M. D. Bruch, A. N. Stroup, and L. M. Gierasch, *Biopolymers*, 1990, **29**, 263)

types of turn. From the interproton distances it was calculated that the population of type II β -turn conformations in the Pro-Asn and Pro-Ala peptides is about 35% and 10%, respectively, which correlates very well with the observed frequency of occurrence of Asn and Ala in the $i + 2$ position of protein type II β -turns.⁸ Equilibrium between type I and type II β -turns in peptides has also been observed by circular dichroism.¹³

The parameters used to recognize β -turns in proteins are in principle analogous to those used for peptides. Identification of β -turns at the ends of β -sheet strands is straightforward because they represent a clear interruption of the regular pattern of NOEs characteristic of β -sheets. However, it is difficult to distinguish type I β -turns at either the N- or the C-terminus of helices, in particular 3_{10} helices, because of the similarity between the NOE patterns associated with both types of secondary structure and the difficulty in measuring accurate interproton distances in proteins. The latter reason, and the lack of a repetitive pattern of NOEs characteristic of β -turns, also hinder the location of β -turns in segments of the polypeptide chain with nonregular secondary structure. Thus, many of the β -turns in proteins cannot be located unambiguously until determination of the tertiary structure with a complete set of short-, medium-, and long-range interproton distances.¹ The type of turn can usually be distinguished from the intensity of the $d_{\alpha N}(i + 1, i + 2)$ NOE, the presence or absence of a $d_{NN}(i + 1, i + 2)$ interaction, and sometimes from tertiary interactions involving the amide proton in position $i + 2$. However, the possibility of interconversion between different turn conformations is hard to assess because of the difficulty in measuring accurate interproton distances.

3 α -HELICES

The α -helix is the most abundant element of secondary structure in proteins, and the structures of some proteins such as those in the globin family comprise only α -helices

and loops. α -Helices are formed by an array of consecutive residues with backbone torsion angles around the standard values indicated in Table 1. Since formation of α -helices requires a minimum number of residues and their stability increases with their length, α -helices are less common than β -turns in the bioactive conformations of short, naturally occurring peptides. However, α -helix formation is a common determinant of biological activity in longer peptides such as growth-hormone releasing factor.

The most characteristic feature to identify the presence of an α -helix by NMR spectroscopy is the presence of a pattern of consecutive, medium-to-strong $d_{\text{NN}}(i, i + 1)$ NOE connectivities, accompanied by numerous $d_{\alpha\beta}(i, i + 3)$, $d_{\alpha\text{N}}(i, i + 3)$, and $d_{\alpha\text{N}}(i, i + 4)$ interactions (Table 1). Some $d_{\text{NN}}(i, i + 2)$ NOEs may also be observed, and $d_{\beta\text{N}}(i, i + 1)$ NOEs are usually stronger than in β -sheet or in random conformations. The less usual 3_{10} helices, which are characterized by similar interproton distances to those of an α -helix, can be distinguished by the regular presence of $d_{\alpha\text{N}}(i, i + 2)$ NOEs and the absence of $d_{\alpha\text{N}}(i, i + 4)$ interactions.¹⁴ α -Helices are also characterized by small $^3J_{\text{HN}\alpha}$ coupling constants. Although the expected value of $^3J_{\text{HN}\alpha}$ is 3.9 Hz for the standard α -helix geometry,² it is unusual to observe such low values for α -helical peptides and, even in regions that have high populations of α -helical conformation, $^3J_{\text{HN}\alpha}$ coupling constants of about 5–6 Hz are usually found. This observation probably reflects the intrinsic flexibility of the polypeptide chain in the absence of the tertiary interactions that stabilize protein structures. Since the large linewidths associated with protein resonances hinder the accurate measurement of small coupling constants, $^3J_{\text{HN}\alpha}$ in proteins are usually classified as ‘large’ (≥ 7 Hz) or ‘small’ (≤ 6 Hz), and α -helices are distinguished by a string of consecutive ‘small’ $^3J_{\text{HN}\alpha}$ coupling constants. Another characteristic of α -helices is that all their amide protons, except those at the N-terminus, participate in CO(i)/HN($i + 4$) hydrogen bonds, which results in decreased H/D exchange rates.

Although peptide and protein chemical shifts have traditionally been difficult to understand in theoretical terms, unequivocal correlations between certain chemical shifts and secondary structure are now well established. Such correlations are based on the differences between the observed chemical shifts and random coil chemical shifts; the differences are known as ‘secondary shifts’ or ‘conformational shifts’. Perhaps the best established correlation is the low-frequency (upfield) conformational shifts of H- α protons in α -helical conformations (on average 0.39 ppm) and the high-frequency shifts for H- α protons in β -sheets (on average 0.37 ppm).¹⁵ A chemical shift index for assigning secondary structure in proteins, based on such shifts, has been described by Wishart et al.¹⁶ In α -helices, amide protons also experience a low-frequency conformational shift,¹⁵ while the $^{13}\text{C}-\alpha$ resonances are shifted to high frequency.¹⁷ Correlations involving H- β and $^{13}\text{C}-\beta$ chemical shifts have also been noted, but are less clear-cut. In general, ^{13}C conformational shifts are more reliable indicators of secondary structure than proton conformational shifts because they are less likely to be affected by other factors such as ring-current shifts from aromatic residues. Although the backbone ^{15}N conformational shifts correlate with those of their directly bonded amide protons, it is more difficult to establish correlations based on backbone ^{15}N chemical shifts because the random coil values are affected by both the side chain of

the same residue and by that of the preceding residue; thus 400 rather than 20 random coil chemical shifts need to be defined. In addition to complementing NOE data in the determination of native three-dimensional structures of proteins by NMR, conformational shifts provide a useful tool for characterizing secondary structure in non-native states of proteins, for which resonance overlap may hinder the obtention of critical NOE data. In peptides, H- α chemical shifts can be used to estimate the relative populations of α -helical conformation at each residue¹⁸ (see below). Other parameters that have been used to obtain such estimates include the intensities of $d_{\alpha\beta}(i, i + 3)$ NOEs,¹⁹ ratios between $d_{\text{NN}}(i, i + 1)$ and $d_{\alpha\text{N}}(i, i + 1)$ NOE intensities,²⁰ and $^3J_{\text{HN}\alpha}$ coupling constants.²⁰

A large number of conformational studies on linear peptides have analyzed the factors that determine α -helix formation and the intrinsic propensities of individual amino acid residues to adopt the α -helical conformation. Structure-inducing solvents such as TFE are often used in these studies to increase the tendency of the peptides to form α -helical conformation. While circular dichroism has been most widely used to evaluate overall helix content in these studies, NMR spectroscopy is the technique of choice for determining the location of the helix and obtaining residue-specific information. An example of these studies is an analysis of the conformations of isolated wild type (WT) and mutant outer membrane protein A (OmpA) signal peptides in membrane mimetic environments, performed to compare the propensities of these peptides to adopt an α -helical conformation with their *in vivo* ability to mediate protein secretion.¹⁸ Figure 3 gives a summary of the $^3J_{\text{HN}\alpha}$ coupling constants and conformationally relevant NOEs observed for the WT OmpA signal peptide in TFE- d_3 /water 1 : 1 (v/v) at 25 °C. These data show that the peptide forms an α -helical conformation throughout most of the sequence, from Lys³ to Ala²¹. The conformational shifts of H- α protons observed for this peptide (Figure 4) agree with this conclusion and show that the helix is somewhat interrupted in the middle of the sequence (near Gly¹⁴), which was confirmed by measurement of H/D exchange rates (not shown). Comparison of the conformational shifts of the mutant peptides with those of the WT peptide (Figure 4) provided a sensitive method for detecting differences among the family

Figure 3 Summary of NOE and $^3J_{\text{H,N-}\alpha}$ data defining the α -helical conformation of the isolated wild type OmpA peptide in TFE- d_3 /water 1 : 1 (v/v). For the sequential NH(i)/NH($i + 1$) interactions, the height of the boxes reflects the NOE intensity. Boxes and solid lines indicate NOEs that could be identified; question marks and dashed lines indicate NOEs whose presence could not be assessed due to resonance overlap. (Reproduced by permission of the American Chemical Society from J. Rizo, F. J. Blanco, B. Kobe, M. D. Bruch, and L. M. Gierasch, *Biochemistry*, 1993, **32**, 4881)

Figure 4 Conformational shift maps for wild type and five mutant OmpA peptides in TFE- d_3 /water 1 : 1 (v/v) (solid lines). The wild type sequence is shown in Figure 3. The L6L8 mutant contains Ile⁶ > Leu and Ile⁸ > Leu mutations, and the 18N peptide contains an Ile⁸ > Asn mutation. The Δ8, Δ9, and Δ6–9 mutants contain deletions at residues Ile⁸, Ala⁹, and Ile⁶–Ala⁷–Ile⁸–Ala⁹, respectively. In the maps for the mutant peptides, the profiles are compared with the wild type profile (dashed lines). (Reproduced by permission of the American Chemical Society from J. Rizo, F. J. Blanco, B. Kobe, M. D. Bruch, and L. M. Gierasch, *Biochemistry*, 1993, **32**, 4881)

of peptides in the populations of α -helix at different residues. Indeed, overall helical contents calculated from the average conformational shifts agreed very well with helical contents calculated from circular dichroism data. The same set of OmpA peptides was also analyzed by NMR in deuterated sodium dodecyl sulfate micelles, revealing a clear correlation between the α -helical contents of the peptides in the micelles and their *in vivo* activity.¹⁸ In addition, comparison with the data obtained in TFE- d_3 /water showed that the correlation was due to a combination of hydrophobic and electrostatic interactions of the peptides with the micelles.

An increasing number of short peptides have been shown to adopt an α -helical structure in aqueous solutions, without the help of organic solvents. Most notable are peptides with sequences corresponding to segments of protein chains that adopt an α -helical conformation in the native structure of the proteins. A classical example is the C-peptide of ribonuclease A (the N-terminal 13-residue segment produced by cleavage with cyanogen bromide). Analysis of this peptide and its analogs by circular dichroism provided ample evidence for the formation of α -helical structure in aqueous solution at low temperatures. An NMR analysis of an analog of the C-peptide in aqueous solution at 3 °C was carried out to determine local conformational effects of α -helix stabilizing interactions in the peptide. A high population of an α -helical conformation extending throughout most of the sequence was observed, but

the α -helix was distorted at the N-terminus to accommodate a salt bridge between the side chains of residues 2 and 10.²¹ The distortion was evidenced by a number of NOEs that are not characteristic of an α -helix. Strikingly, the same salt bridge and a similar distortion of the helix is observed in the X-ray structure of ribonuclease A. In another study of the tendency of isolated segments of proteins to adopt native secondary structure, a peptide corresponding to the H-helix of myoglobin was analyzed by NMR in aqueous solution.¹⁹ The peptide was shown to adopt an α -helical conformation that is most stable in the middle of the sequence and frays at both termini. The H-helix is present in a molten globule state of apomyoglobin, and is one of the first elements of secondary structure formed in the folding pathway of the protein, as evidenced by H/D exchange pulse labeling experiments monitored by NMR.²² These and other studies have shown that certain α -helices present in the native structures of proteins can be formed as independent folding units, and thus could act as initiators of protein folding.

The α -helical regions of proteins are characterized by small dispersion of chemical shifts, and severe overlap usually hinders the sequential resonance assignment. Use of heteronuclear three-dimensional NMR experiments²³ such as ¹H–¹⁵N three-dimensional TOCSY–HMQC (heteronuclear multiple quantum coherence) and three-dimensional NOESY–HMQC can greatly alleviate this problem. Indeed, if there is no simultaneous degeneracy of amide ¹H and ¹⁵N chemical shifts, the

Figure 5 Assignment of the second helix of CRABP illustrated with (ω_1, ω_3) strips from a ^1H – ^{15}N three-dimensional NOESY–HMQC spectrum, taken at ω_2 values corresponding to the ^{15}N chemical shift of the amide nitrogen of each residue. Boxes indicate intraresidue NOEs, arrows point to sequential NOEs involving H- α or side-chain protons, and solid lines indicate $d_{\text{NN}}(i, i + 1)$ connectivities. Dashed lines indicate $d_{\text{NN}}(i, i + 2)$, $d_{\alpha\text{N}}(i, i + 3)$, and $d_{\alpha\text{N}}(i, i + 4)$ NOEs

characteristic NOE patterns associated with the α -helical conformation make it straightforward to sequentially assign α -helical regions from the sets of NOEs observed for each amide proton. This point is illustrated in Figure 5, where selected strips of a ^1H – ^{15}N three-dimensional NOESY–HMQC spectrum of cellular retinoic acid binding protein (CRABP),²⁴ corresponding to part of one of the two α -helices of this protein, are shown. The sequential assignment can be easily performed from the $d_{\text{NN}}(i, i + 1)$ connectivities alone. Numerous sequential and $d_{\alpha\text{N}}(i, i + 3/4)$ NOEs provide additional information for resolving possible ambiguities in the interpretation of the $d_{\text{NN}}(i, i + 1)$ interactions. A feature which also facilitates the assignments is the fact that, because any two consecutive amide protons in a helix are close to each other, there is usually a good number of protons that are simultaneously close to both amide protons; thus, consecutive amide protons generally have many NOEs in common (sometimes more than 10).

For proteins with molecular weight above 10 kDa and containing mostly α -helical conformation, severe resonance overlap may hinder the sequential assignment even using ^1H – ^{15}N three-dimensional TOCSY–HMQC and NOESY–HMQC data. These problems can be overcome using a series of triple resonance experiments on uniformly ^{15}N - and ^{13}C -labeled protein samples, which provide two and sometimes three different pathways to the sequential assignments.²⁵ The power of these experiments was demonstrated in the analysis of the mostly α -helical protein calmodulin (16.7 kDa)^{25,26} and of its complex with a 26-residue peptide derived from skeletal muscle myosin light chain kinase.²⁷ Calmodulin is a Ca^{2+} binding protein that regulates the activity of a large number of proteins. The structure of calmodulin contains two domains, with two helix–loop–helix ‘EF-hand’ Ca^{2+} binding domains each, that are connected by a long central helix. While the central helix appears to be continuous in the crystal structure of calmodulin, NMR analysis showed that four residues in the middle of the helix were actually quite unstructured and flexible in solution,²⁶ allowing the N- and C-terminal domains to tumble independently.²⁸ Solution of the structure of the complex with

the 26-residue peptide showed that the peptide binds in an α -helical conformation, and that the central helix of calmodulin unravels further upon peptide binding, thus (using the words of the authors) ‘enabling the two domains to come together to grip the peptide rather like two hands capturing a rope’.²⁷ The structure of the complex also explained how calmodulin is able to bind a variety of polypeptide chains.

4 β -SHEETS

β -Sheets constitute the second most abundant type of regular secondary structure found in proteins. In contrast to turns and helices, β -sheets are not usually formed by a single segment of a polypeptide chain, but rather by at least two segments aligned in a parallel or antiparallel arrangement so that the amide groups of one segment form hydrogen bonds with the amide groups of the other segment (Figure 1). In addition, β -sheets are stabilized by nonbonding interactions between the side chains of the two strands. Thus, in the case of β -sheets, the formation of secondary structure is coupled to the establishment of tertiary interactions. Consequently, β -sheets are unusual in the conformations of monomeric peptides in solution, and β -sheet formation in peptides is most often concomitant with aggregation. However, interaction with a receptor can stabilize β -structure, and short β -hairpins, where two peptide segments connected by a β -turn form an antiparallel β -sheet, have been proposed to be present in the bioactive conformations of some naturally occurring peptides, e.g. GnRH.¹¹

The torsion angles characteristic of both parallel and antiparallel β -sheets (Table 1) correspond to extended conformations of the polypeptide chain and the associated patterns of sequential NOEs are similar to those of random coils: $d_{\alpha\text{N}}(i, i + 1)$ NOEs are strong, $d_{\text{NN}}(i, i + 1)$ NOEs are very weak or absent, and $d_{\beta\text{N}}(i, i + 1)$ NOEs are usually weaker than in α -helices. No $d(i, i + 2)$, $d(i, i + 3)$, or $d(i, i + 4)$ interactions are usually observed in β -sheets. However, interstrand NOEs (Table 1)

can help distinguish β -sheets from nonspecific extended conformations. Among these interactions, medium-to-strong $d_{\alpha\alpha}$ NOEs are the hallmark of antiparallel β -sheet structure, while other interstrand NOEs in either parallel or antiparallel β -sheets are usually weak. The identities of the interstrand NOEs provide unequivocal evidence of the relative orientation of the strands, and thus distinction between parallel and antiparallel β -sheets is straightforward from such NOEs. β -Sheets are also characterized by large (≥ 8.0 Hz) $^3J_{\text{HN}\alpha}$ coupling constants. Most amide protons in β -sheets have decreased amide H/D exchange rates due to hydrogen bonding, except at the edges where alternate amide protons are exposed to the solvent. High frequency conformational shifts are observed in general for H- α and HN protons in β -sheets,¹⁵ while $^{13}\text{C}-\alpha$ resonances are usually shifted to low frequency.¹⁷

The structural factors that influence the adoption of β -sheet structure are less well understood than those determining α -helix formation, due in part to the fact that peptides with a propensity to form β -structure usually have also a high tendency to aggregate. Nevertheless, an example of a short linear peptide adopting a substantial population of a β -hairpin conformation in solution has been reported recently.²⁹ This peptide, with sequence YQNPDGSQA, was designed as an analog of the segment 15–23 of tendamistat (YQSWRYSQA), which forms a β -hairpin in the native protein; the four residues NPDG were introduced to optimize the probability of β -turn formation. Analysis by NMR showed that the peptide YQNPDGSQA exists in equilibrium among multiple conformations in solution, but a significant population of a β -hairpin structure was demonstrated by the observation of several interstrand NOEs, including a Gln² H- α /Gln⁸ H- α interaction. A control nonapeptide including the NPDG sequence did not adopt the β -hairpin conformation, indicating that the residues flanking the β -turn play a role in stabilization of the β -hairpin. Other examples of monomeric peptides forming β -sheets have involved the use of covalent constraints.

A good example of peptide β -hairpins stabilized by cyclization has been provided by a series of peptides derived from the flap of human renin, a β -hairpin loop that corresponds to a strongly antigenic region of the protein.³⁰ The peptides contained eight or twelve residues from the sequence of the flap and two cysteines, one at each termini, forming a disulfide bond. NMR analysis of the peptides showed several interstrand NOE interactions characteristic of the proposed β -hairpin structure. The two cyclic peptides were recognized by human renin antibodies, while their linear analogs did not bind to the antibodies. Disulfide bonds have also been used in the design of constrained peptide models for β -sheets, and continuing progress is being made in the improvement of such models, as well as in the design of β -sheet nucleating templates (see Rizo and Gierasch³). These molecules will be very useful tools for studying the rules that determine β -sheet formation in polypeptides.

The NMR spectra of proteins containing mostly β -structure generally have good dispersion of chemical shifts, which facilitates their sequential assignment. It is typical to observe abundant H- α resonances above 5 ppm and amide proton signals between 9 and 10 ppm. The large dispersion of chemical shifts arises in part from diversity in the backbone torsion angles, since the β -structure corresponds to the widest region of energetically favorable conformations in the Ramachandran map; thus, larger deviations from standard geometries are observed in β -sheets than in α -helices. Selected strips corresponding to a $^1\text{H}-^{15}\text{N}$ three-dimensional NOESY-HMQC spectrum of CRABP, a 136-residue protein with two five-stranded antiparallel β -sheets and a helix–turn–helix motif,²⁴ are shown in Figure 6. The strips illustrate the assignment of the C-terminal β -strand (residues 128–136) which, in the tertiary structure of the protein, is contiguous to the segments 7–14 and 117–123. The sequential assignment is based primarily on the strong $d_{\alpha\text{N}}(i, i+1)$ NOEs, and the observation of some sequential connectivities involving side chains provides checks for

Figure 6 Assignment of the C-terminal β -strand of CRABP illustrated with (ω_1, ω_3) strips from a $^1\text{H}-^{15}\text{N}$ three-dimensional NOESY-HMQC spectrum, taken at ω_2 values corresponding to the ^{15}N chemical shift of the amide nitrogen of each residue. Boxes indicate intrasidue NOEs and arrows point to sequential NOEs involving H- α or side-chain protons. Long range NOEs corresponding to interstrand interactions have been labeled

the assignments. However, consecutive amide protons in β -sheets have, in general, many fewer NOEs in common than in α -helices, and thus it is more difficult to ensure the correctness of the sequential assignment when there is degeneracy in the H- α chemical shifts. For proteins the size of CRABP and larger, such degeneracy is common, despite the good chemical shift dispersion, and the difficulty in the assignment is further compounded by the lack of residue type information for many amide protons, due to the absence of many relayed connectivities between amide and side-chain protons in ^1H - ^{15}N three-dimensional TOCSY-HMQC data. NMR analysis of selectively ^{15}N -labeled protein samples can be of great help in circumventing these problems,²⁴ or, alternatively, the assignment can be performed using the triple resonance experiments cited above, which are not based on NOE interactions and can be applied independently of the type of secondary structure.²⁵

Once the sequential assignments of a β -sheet protein have been obtained, the observation of numerous interstrand NOEs (see Figure 6) offers additional checks for the assignments. As mentioned above, the strongest of these interactions in

antiparallel β -sheets are $d_{\alpha\alpha}$ NOEs, which do not appear in the ^1H - ^{15}N three-dimensional NOESY-HMQC data but can be easily identified in two-dimensional NOESY spectra obtained in D_2O . As an example, Figure 7 shows the α/α region of a NOESY spectrum of the mostly β -sheet protein interleukin 1 β .³¹ The $d_{\alpha\alpha}$ cross peaks are usually well resolved because of the almost complete absence of other types of interaction in this region of the NOESY data, and because of the small likelihood that a pair of interacting H- α protons in a β -sheet has both H- α chemical shifts identical to another H- α /H- α interacting pair. The interstrand NOEs yield critical information on the relative positions and orientations of the β -strands in the three-dimensional structure of the protein. Indeed, due to the large number of tertiary interactions involving exclusively backbone protons, assignment of the backbone resonances and of the secondary structure elements in predominantly β -sheet proteins can often yield a rather good model for the overall folding of the protein. This situation is in contrast with α -helical proteins, where tertiary packing of different polypeptide chain segments involves more side-chain/side-chain contacts and fewer backbone/backbone

Figure 7 Expansion corresponding to the H- α /H- α region of a NOESY spectrum of interleukin 1 β in D_2O . Labeled cross peaks correspond to $d_{\alpha\alpha}(i,j)$ NOEs. (Reproduced by permission of the American Chemical Society from P. C. Driscoll, A. M. Gronenborn, P. T. Wingfield, and G. M. Clore, *Biochemistry*, 1990, **29**, 4668)

interactions. On the other hand, the larger number of short range NOEs observed in α -helical proteins enable a more facile definition of the local chain conformation. As a consequence of the smaller number of short-range interactions and larger deviations of the torsion angles from standard values, good definition of the local conformation in β -sheet proteins cannot be achieved until determination of the complete three-dimensional structure. Interestingly, these NMR observations may reflect fundamental differences between the mechanisms of folding of mostly α -helical and mostly β -sheet proteins.

1 INTRODUCTION

Peptide hormones and neurotransmitters¹ are chemical messengers found throughout the animal kingdom that are critical for intercellular communication, for integration of responses to outside stimuli, for maintenance of homeostasis, and for control and development of life. In animals they control, modulate, or stimulate such diverse biological functions as growth, pigmentation, learning, digestion, cardiovascular function, kidney function, pain, glucose production, metabolic rates, and many others. Hence, efforts to understand the relationships of their structures to biological activities have been of great interest to scientists and medical doctors since they have great potential for the control and cure of many diseases.

Historically, a peptide hormone was defined as a polypeptide produced in one cell type, released from that cell in response to a stimulus, and biologically active at some other cell. The cells involved could be far apart (e.g. oxytocin—found in the pituitary gland and having its effect at the uterus), or close together (e.g. somatostatin—found in cells in the pancreas adjacent to glucagon and insulin containing cells). In all cases, however, their biological function is initiated by interactions with receptors found in the plasma membrane. Recently, many of these receptors have been isolated and their structures determined by cloning.

Though some peptide hormones are proteins with over 100 to several hundred residues (e.g. growth hormone, luteinizing hormone, etc.), most are small peptides (3–60 residues). They are formed by the processing of larger precursor proteins that generally are not biologically active (presumably because the recognition site on the hormone is partially or completely inaccessible for interaction with its receptor). Usually the peptide hormone or neurotransmitter is found in secretory granules where it is stored pending a signal to release it.

The fact that most peptide hormones are small peptides has presented difficulties in determining their conformation in solution and their conformational structure–biological activity relationships. NMR studies have demonstrated multiple conformational properties for many of these compounds. This has stimulated efforts to develop approaches to stabilizing or restricting these conformations that are compatible with potent

biological activity so that NMR could be used to help determine the ‘bioactive’ conformation.

In this article we discuss how specific aspects of NMR methodology can be used in conjunction with biological and other biophysical considerations for conformational analysis of peptide hormones and its relation to biological activity, and then provide a few examples from the literature. There is no opportunity in the space allotted to be comprehensive (in 1973 a comprehensive review² had over 700 references). We apologize to the many contributors whose work is not discussed here.

2 STRUCTURE: BIOLOGICAL CONSIDERATIONS

Since most peptide hormones are small, linear polypeptides, they tend to have multiple conformations in solution, and these conformations generally interconvert rapidly on the NMR timescale. Hence NMR analysis may lead to the erroneous result of an ‘average’ conformation that may not reflect any specific conformation. This problem was recognized at an early stage using NMR and other biophysical methods,² and led several laboratories to develop approaches to overcome it.

One approach that has been taken is to lower the temperature to -80°C or lower in cytoprotective solvents. However, many peptides still appear to have multiple conformations and it has been difficult to determine a single conformation. In cases where conformational insights have been obtained, it generally has not been clear whether they are of biological significance.

The more general approach has been that of conformational constraints.^{3–7} In this approach specific conformational constraints involving unusual amino acid residues, cyclization, or other structural perturbations are introduced and their effects on biological activity examined. If the design has been consistent with the structural, conformational and dynamic requirements of the receptor, biological potency can be maintained or even enhanced. Alternatively, the properties may be inconsistent for interaction with the receptor and the biological potency will be greatly reduced. In either case, if the conformation is sufficiently rigid, NMR and other biophysical studies can be performed that can provide unique insights into peptide conformation–biological activity relationships. The most useful situation is when structurally closely related, conformationally restricted, peptides with greatly diverse biological potency can be examined and compared to provide insight, and in some cases a pharmacophore model. Some general methods of conformational constraint are given in Table 1 (a few excellent reviews and overviews are indicated^{3–7}). In addition, the use of very large peptide and nonpeptide libraries (see e.g. Houghton et al.⁸ and Lam et al.⁹) can provide another general method of obtaining a lead structure.

In all cases it is generally necessary to utilize more than one biological assay. Many (most) peptide hormones have multiple biological effects (in terms of the receptor, multiple receptor types, and subtypes). Hence if insights into the conformational structure requirements for selectivity and specificity are to be obtained, multiple assays are needed. Indeed, since it often has been found that conformational constraints provide peptide analogs with enhanced selectivity, much information can be lost unless multiple assays are utilized.

2 PEPTIDE HORMONES

Table 1 Methods of Conformational Constraint That Have Proven Useful for Peptide Conformation Activity Studies

Local Constraints	Global Constraints
N ^α -Alkyl or Aryl	Disulfide ring
C ^α -Alkyl or Aryl	Sulfide, lactam, lactone or macrocyclic ring
C ^β -Alkyl, Aryl, OH, etc. (χ constraint)	N- to C-terminal cyclic
β,β -Dialkyl cysteine	Side chain to N- or C-terminal cyclic
D-Amino acids	Side chain to backbone cyclic
Reverse turn mimetic or mimic	Backbone to backbone cyclic

Table 2 NMR Criteria for Establishing Conformational Homogeneity

1.	Large differences in chemical shifts and coupling constants of similar amino acids in the peptide
2.	Significant chemical shift differences for diastereotopic protons or groups
3.	Large differences in chemical shifts and temperature dependencies
4.	Large deviations in the coupling constants from the mean value of about 7.5 Hz
5.	Linearity of temperature dependence of NH chemical shift and/or no dependence of NH proton chemical shifts
6.	No change in chemical shifts or coupling constants with concentration
7.	Independence of spectral parameters with solvent change

3 GENERAL STRATEGY FOR CONFORMATIONAL ANALYSIS OF PEPTIDES USING NMR

Despite the caveats given above, it often is useful to use NMR to examine short linear peptides of biological significance for proof of structure, evidence for *cis-trans* isomerism, examination of conformational flexibility, and determination of anisotropic effects or unusual NOEs that provide insights into an overall conformation which may be useful for design of constraints. In addition, using labeled (²H, ¹³C, ¹⁹F, etc.) peptides it is possible to obtain insights into peptide hormone–receptor/acceptor interactions using NMR techniques. Such studies will not be discussed here for lack of space, but useful reviews are available.^{10,11} A major emphasis here is to outline those approaches where conformational constraints have been sufficient to lead to a peptide or peptide mimetic with a preferred conformation. It will be recognized that the conformation of the backbone will be most easily obtained, whereas, unless some local constraint has been introduced, side-chain conformation determination will still be difficult.

Criteria that are generally applied from NMR as evidence of conformational homogeneity are listed in Table 2 (see also Kessler³). Not one of these criteria is in itself conclusive, nor do all have to be satisfied without exception. Rather, when all the criteria are met, with explainable deviations, generally one can conclude that the peptide has a strong conformational preference.

With the above caveats in mind, a general strategy for conformational analysis can be outlined (Table 3). First, all

nuclei observed (¹H, ¹³C, etc.) must be correctly assigned. In general, one begins by obtaining a high-resolution one-dimensional ¹H NMR spectrum using the highest field possible. Since most amino acids are chiral, β and further removed protons generally are prochiral. Thus, spectra often rapidly become quite complex. The closer one can approach first-order spectra, the more accurate NMR parameters can be obtained. The general spectral characteristics for each amino acid residue are well established,^{12,13} and in many cases assignments can be made by recognition of subspectra associated with particular residues. In favorable cases accurate coupling constants also can be obtained. In most cases one needs to turn to two-dimensional NMR techniques. A large, increasing number of techniques are available to obtain a variety of information. Space does not permit a detailed discussion of how to proceed, but a general outline follows.

When strong proton overlap occurs, double quantum (DQ) COSY experiments, relayed H–H COSY, and TOCSY experiments are recommended. Occasionally, indirect methods of detection are needed (H–C COSY, etc.). For assignment of carbon or nitrogen signals, H–X COSY experiments are utilized. Particularly important in some cases is the assignment of the carboxyl carbon atoms. Since they have no attached proton, ¹H- α , ¹³C' coupling is needed.

Once all the subspectra have been assigned, it is necessary to obtain the complete sequence of the peptide. For this purpose, interactions across the peptide bond are needed. Essentially two approaches are possible: homonuclear (e.g. C _{α} ^{*i*}H–N _{α} ^{*i+1*}H, four bond, difficult) or heteronuclear (e.g. C _{α} ^{*i*}H–N _{α} ^{*i+1*}H, three bond, possible) through-bond coupling. In all cases success depends on the presence of unique amino residues, or unambiguous starting points to ensure that the correct sequence assignments are made. In any case, proton–proton coupling across amide bonds is only of limited use, whereas heteronuclear coupling [for example to assigned carboxyl (C') carbons] is more reliable for obtaining sequence information.

Experience has shown that often it is necessary to utilize alternative through-space connectivities. In this case, sequential neighboring amino acid ¹H spin systems are identified by the use of through-space NOE connectivities. Most commonly these involve C _{α} ^{*i*}H–N _{α} ^{*i+1*}H and/or N _{α} ^{*i*}H–N _{α} ^{*i+1*}H connectivities, though in some cases C _{β} ^{*i*}H–N _{α} ^{*i+1*}H connectivities can be observed. Generally the chemical shift information does not provide direct conformational information (however, see e.g. Jiao et al.¹⁴).

Conformational analysis depends on utilizing NMR spectral parameters that are directly dependent on spatial arrangements. In addition, temperature dependence of peptide amide protons and chemical shift effects as a result of anisotropy can be very useful.

Table 3 General Strategy for Obtaining NMR Parameters Needed for Peptide Conformational Analysis

Evidence	NMR Methods
Complete assignments	One-dimensional ^1H , ^{13}C high-resolution spectra; ^1H - ^1H COSY; ^1H - ^{13}C COSY; TOCSY; NOESY, ROESY; HMQC; Heteronuclear inverse detection; etc.
Accurate determination of chemical shifts	As above; <i>cis-trans</i> XAA-Pro- ^{13}C - β and - γ
Accurate determination of coupling constants	One-dimensional NMR; phase-sensitive H-H COSY and 2QF COSY; spectral simulation; z filtered heteronuclear HMQC-TOCSY; etc.
Quantitative determination of NOEs	Phase-sensitive NOESY; one-dimensional difference; ROESY

Once all the NMR parameters have been obtained, several possible conformations may satisfy most of the NMR parameters. To obtain the most reliable conformation, molecular dynamics (MD) simulations generally are required. Both homo- and heteronuclear coupling constant constraints and NOE distance constraints are needed to derive a conformation that will satisfy all the NMR parameters.^{15,16} Conformations consistent with X-ray data for crystalline peptides and with NMR data have been obtained in a few cases.

4 CONFORMATIONAL ANALYSIS: RELATION TO BIOLOGICAL ACTIVITY AND SELECTED EXAMPLES

4.1 Oxytocin

Oxytocin (OT; H-Cys-Tyr-Ile-Gln-Asn-Cys-Pro-Leu-Gly-NH₂), has a special place in peptide hormone chemistry, since it was the first peptide to be isolated and its structure proven by total synthesis. For this work Vincent du Vigneaud received the Nobel Prize in Chemistry in 1955. Since then, OT has played a pivotal role in the development of strategies for determining hormone structure-activity relationships.¹⁷ It was the first peptide hormone for which a conformation in solution (dimethyl sulfoxide; DMSO) was proposed based primarily on NMR studies,¹⁸ and for which a complete analysis of the NMR in aqueous solution was provided.¹⁹ Based on the NMR results and known structure-activity relationships, Walter²⁰ proposed the 'cooperative model' for oxytocin activity at the uterine receptor. Based on ^1H NMR studies of a conformationally constrained antagonist, [1-penicillamine]oxytocin ([Pen¹]OT; Pen, β,β -dimethylcysteine)²² and other antagonist analogs, Hruby and co-workers proposed a conformational and dynamic model that distinguished antagonists from agonists^{17c,21} and led to the suggestion that oxytocin agonists and antagonists have different conformational structure-biological activity relationships.^{17c,22}

Subsequently, an X-ray crystal structure of the highly potent agonist, desamino-oxytocin ([β -Mpa¹]OT; β -Mpa, β -mercaptopropionic acid) was determined.²³ Two conformations were found in the unit cell with opposite disulfide chiralities. A β -turn in the ring involving the Tyr-Ile-Gln-Asn sequence proposed from NMR was found in both structures.

More recently, NMR studies using the transfer NOE and extensive constrained molecular dynamics and molecular

Figure 1 Stereoviews of the crystal structure of (a) deamino-oxytocin and (b) the NMR conformation of oxytocin bound to neurophysin I

mechanics calculations, have led to the determination of the conformation of oxytocin bound to its carrier protein in neurosecretory granules, neurophysin I.²⁴ A much different conformation from that of deamino-oxytocin in the crystal or solution state was observed (Figure 1).

Very recently, using two-dimensional NMR methods in conjunction with extensive molecular dynamics simulations and molecular mechanics calculations,²⁵ the conformation of the highly potent bicyclic oxytocin antagonist analog [β -Mpa¹, Glu⁴, Cys⁶, Lys⁸]OT²⁶ was determined, which included a β -turn in the 20-membered disulfide bridge involving the Cys-Tyr-Ile-Glu sequence and a *cis* Cys⁶-Pro⁷ peptide bond. This quite rigid bicyclic conformation provides a different topographic presentation of the Tyr² (and other) side-chain groups, and an excellent model for a bioactive conformation for OT antagonists.

4.2 Somatostatin

The cyclic peptide H-Ala-Gly-Cys-Lys-Asn-Phe-Phe-Trp-Lys-Thr-Phe-Thr-Ser-Cys-OH, which has a variety of proposed biological activities (including inhibition of the release

of growth hormone from the pituitary, and insulin and glucagon from the pancreas), serves as an excellent example of the use of conformational thinking in conjunction with NMR for peptide design. The suggestion by Veber and co-workers of a β -turn about the Phe-Trp-Lys-Thr sequence was supported by structure–activity studies and NMR,²⁷ and led through a series of cyclic peptides of increasingly reduced ring size to the cyclic hexapeptides c(Pro-Phe-D-Trp-Lys-Thr-Phe) and c(N-MeAla-Phe-D-Trp-Lys-Thr-Phe),²⁸ which were found to be highly potent. Subsequently, extensive NMR studies on these compounds by Kessler et al.²⁹ and by Veber³⁰ have provided direct evidence that a type II' β -turn about the D-Trp-Lys residues was a low energy structure, and topographical features important to biological activity have subsequently been investigated by NMR.³¹ In a very interesting study, Kessler et al.³² made retro-analogs of the cyclic hexapeptide series which had cytoprotection activity in the inhibition of cholate uptake in isolated hepatocytes, and greatly reduced or completely suppressed somatostatin-like activity.

Highly potent and selective disulfide-containing analogs of somatostatin have been prepared such as D-Phe-Cys-Phe-D-Trp-Lys-Thr-Cys-Thr-(ol) (SMS 201-995) which is a superpotent somatostatin analog³³ and also has some opioid-like activities. Conformational analysis using NMR indicated that these compounds retained the β -turn conformation about the Phe-D-Trp-Lys-Thr sequence with a γ -turn also possible.³⁴ Utilizing this β -turn template it was possible to design cyclic analogs with high potency and selectivity for μ opioid receptors such as D-Phe-Cys-Tyr-D-Trp-Lys-Thr-Pen-Thr-NH₂³⁵ (CTP) and greatly reduced (1000 fold) somatostatin-like activity. The use of topographical constraints in χ space (χ_1 and χ_2 constraints) in conjunction with the β -turn structure, and careful conformational analysis using NMR^{36,37} led to a detailed understanding of the conformational and topographical properties of D-Tic-Cys-Tyr-D-Trp-Arg-Thr-Pen-Thr-NH₂ (Tic, 1,2,3,4-tetrahydroisoquinoline-3-carboxylate) which has no somatostatin-like activity and is highly μ opioid selective. This suggests that there should be considerable similarities, but some differences, in μ opioid receptors and somatostatin receptors. Recently, both these receptor types have been cloned, and the somatostatin and μ opioid receptors have extensive sequence homology. Interestingly, some of these constrained peptides also have considerable agonist potency at δ opioid receptors. It is fascinating that a single ligand can be agonist at one receptor type and an antagonist at other.

4.3 Opioid Peptides

Since the discovery of [Leucine⁵]- and [Methionine⁵]-enkephalin (H-Tyr-Gly-Gly-Phe-Leu-OH and H-Tyr-Gly-Gly-Phe-Met-OH, respectively) in the mid-1970s, much has been done to examine the possible conformations of these and other endogenous peptides such as the dynorphins [e.g. dynorphin A (1–11), (Tyr-Gly-Gly-Phe-Leu-Arg-Arg-Ile-Arg-Pro-Lys-OH), the dermorphins (H-Tyr-D-Ala-Phe-Gly-Tyr-Pro-Ser-NH₂), the deltorphins (e.g. deltorphin I, H-Tyr-D-Ala-Phe-Asp-Val-Val-Gly-NH₂) and dermenkephalin (H-Tyr-D-Met-Phe-His-Leu-Met-Asp-NH₂)]. Though early NMR studies were made,³⁸ no general consensus developed regarding their conformation in solution or their bioactive conformation.³⁹ Furthermore, it became increasingly evident that several

types of opioid receptor (δ , μ , and κ) were present in animals, and thus it was necessary to examine the bioactive conformations of these compounds for the different requirements of each opioid receptor type. This led to the design of conformationally constrained cyclic analogs some of which were highly potent opioid receptor selective cyclic compounds,⁴⁰ including: H-D-Pen-Gly-Phe-D-Pen-OH (DPDPE) (δ selective); H-Tyr-D-Cys-Phe-D-Pen-LH (JOM-13) (δ selective); H-Tyr-D-Orn-Atc-Glu-NH₂ (μ selective); H-Tyr-D-Pen-Phe-Asp-Pen-Val-Gly-NH₂ (δ selective); and H-Tyr-Gly-Gly-Phe-Cys-Arg-Arg-Ile-Arg-Pro-Cys-NH₂ (κ selective). Extensive NMR and related studies have been made on these and related compounds. From these studies a consensus is emerging regarding likely conformations for these compounds,^{41–44} and predictions regarding likely bioactive conformations. The use of χ_1 and χ_2 constrained aromatic amino acid derivatives with preferred side-chain conformations provides, in conjunction with NMR, further insights regarding the topographical requirements for agonists and antagonists.^{45–48}

4.4 Others

Numerous other NMR studies have been made on many peptide hormones and neurotransmitters, including insulin, glucagon, luteinizing hormone releasing hormone, α -melanotropin, endothelin, vasopressin, substance P, and other tachykinins, cholecystokinin, angiotensin, bradykinin, etc., and these have led to new insights into the conformational and dynamic properties of these compounds and their analogues.

5 FUTURE PERSPECTIVES

Investigations of peptide hormones by NMR have a very bright future due to the coincidence of rapid developments in several areas. First, the rapid expansion of NMR technology in terms of sensitivity, dispersion, and control of nuclear spin state. Many of the peptide hormones and neurotransmitters have 'simple' structures but they interact with complex receptor systems which include the membrane bound receptor and associated proteins such as G proteins, and currently most are being cloned and expressed. Though it still is not possible to express these in quantities sufficient for NMR and X-ray crystallography studies, this is changing rapidly. There are rapid advances being made in the design and synthesis of the peptide hormones themselves, and of analogs constrained in ϕ, ψ space and in χ space, including advances in synthetic methodology related to asymmetric synthesis. The ability specifically to design in isotopes, reporter moieties, and other 'structures' of interest for use by the NMR spectroscopist will greatly aid in continued rapid development.

Finally, all these advances are being enhanced and catalyzed by the rapid developments of computer software which greatly aid not only in the analysis of NMR data but also in computer assisted design of peptide and peptidomimetic ligands and in strategies for these syntheses. The power of NMR to help analyze these systems will play an increasingly powerful role in developing an understanding of these very important molecules.

1 INTRODUCTION

Peptides are responsible for a wide range of biological functions. They can act, for example, as hormones, neurotransmitters, or inhibitors. The three-dimensional structure of bioactive peptides defines their specific function. Hence, structure determination of active compounds and analogs is the basis for peptide-derived rational drug design. In addition, the analysis of the conformational space of linear peptides and protein fragments becomes increasingly interesting as a model to understand the pathways of protein folding.

In general, peptides are flexible molecules adopting many conformations that interconvert rapidly on the NMR timescale. In particular, linear peptides up to about 15 residues do not normally show a defined secondary structure. Such peptides often exhibit only a slight preference for some parts of their conformational space,¹ which may not coincide with the bioactive conformation when bound to its receptor. They usually adopt their 'active conformation' via an induced fit toward the receptor or by interaction with a hydrophobic environment, namely membranes. Larger polypeptides containing more than about 20 amino acids often already form secondary or tertiary structural elements (like α -helices or β -bends) that are defined by the primary structure, i.e., the peptide sequence. Some rules for the preference of distinct amino acids to form secondary structures have been applied to protein structure prediction (Chou–Fasman^{2,3}). In β -turn structures the $i + 1$ position is often occupied by proline, N -alkylated or D-amino acids.¹ In proline or N -alkylated amino acid containing peptides an equilibrium between the *cis* and *trans* isomers at the peptide bond is often found. In some cases the *cis* isomer is populated up to 50%. However, it is not yet possible to predict unequivocally protein structures from their primary sequences.

A second factor for the stabilization of a particular conformation is the environment, namely the solvent. Trifluoroethanol (TFE) or mixtures of TFE and water are found to stabilize α -helices.^{4,5} Cryomixtures such as dimethyl sulfoxide (DMSO) and water (80:20) allow the measurement of NMR spectra in a solvent of similar polarity to water, but at a lower temperature to slow down conformational exchange.^{6–8}

Also methanol can be used successfully for low-temperature measurements.^{9,10} Peptides in sodium dodecyl sulfate (SDS) micelles often show a preferred conformation,¹¹ whereas in isotropic solvents such as water or DMSO a random coil structure is observed.¹² For structure–activity studies the best method to reduce the flexibility is cyclization.¹³ Due to steric strain and the reduced number of degrees of freedom small cyclic peptides often prefer only a single backbone conformation. If this leads to high biological activity the structure thus obtained is assumed to be close to the bioactive conformation, especially when the conformation is not changed in different solvents. Incorporation of D-amino acids, proline, or turn mimetics into such small cyclopeptides can be used for a screening of the conformational space.¹⁴

For the determination of peptide structures by NMR spectroscopy it is also necessary to be aware of the dynamics and the influence of the environment on the conformational equilibrium. An example of the influence on conformation induced by the environment is cyclosporin A, a cyclic undecapeptide that has been studied in several different solvents [chloroform-*d* (CDCl₃),^{15–17} benzene,^{15–17} tetrahydrofuran (THF),¹⁸ CD₃OD¹⁹], with the addition of lithium salts,²⁰ and in the crystal state,¹⁷ as well as when bound to its natural receptor cyclophilin.^{21,22}

A large number of NMR pulse sequences exist which have been the subject of many reviews.^{23,24} Here we concentrate on those that are essential for the assignment and the extraction of conformationally relevant parameters in peptides.^{25–27} The modular structure of peptide spectra, resulting in separate spin systems for each amino acid, facilitates structural analysis, but the more or less free rotations about bonds to the α -carbons (about angles ϕ , ψ , and χ_1) as well as the side chains, make the determination of their three-dimensional (3D) structures problematic. To analyze such flexible compounds one has to get as many experimental restraints as possible. Apart from NOE or rotating frame Overhauser enhancement (ROE) effects, homo- and heteronuclear coupling constants and temperature coefficients of the H_N protons are the most important. NOE or ROE intensities should be quantitatively converted into distances. The classification as strong, medium, and weak, often used for proteins, is not sufficient for peptides. Conformational averaging is different for NOEs, for J coupling constants and for molecular geometry over a trajectory of a molecular dynamic (MD) calculation.²⁸

Compared with proteins the surface-to-core ratio of (small) peptides is much larger. This not only leads to the high sensitivity of peptide conformations to environmental effects (see above) but also leads to a reduced number of NOE/ROE data. For a reliable analysis of peptide conformations and dynamics, this has to be taken into account by providing enough carefully assigned (including stereochemical assignments) and quantitatively well-determined data. Nonagreement of NOE or J coupling derived structures can be used to identify conformational heterogeneity.

2 ASSIGNMENT OF RESONANCES

The first step of spatial structure determination is the assignment of all resonances.²⁹ Correct assignment provides the proof of the constitution (connectivity) of the peptide. The structures (constitutions) of many naturally occurring

peptides have been established by NMR. For this purpose a complete assignment of all resonances (including, for example, diastereotopic β -protons) is not required. However, for the determination of the 3D structures full assignment is a must.

The experiments to be chosen depend on the complexity of the structure, the amount of compound available, spectrometer equipment, and available measuring time. Complete assignment is normally achieved by using only a few experiments. COSY and TOCSY lead to the assignment of the spin systems, whereas NOESY or ROESY experiments give sequential connectivities. In some cases, for example, similar spin systems or larger sequences, more sophisticated heteronuclear two-dimensional (2D) or even 3D techniques have to be used. Generally the scheme in the following sections is applied for the assignment (see also Table 1).

2.1 Identification of the Nature of the Amino Acid

2.1.1 Classification According to Their Spin System

The spin systems of each amino acid (HN–H- α –H- β . . .) can be determined using the direct proton correlation obtained by a double quantum filtered (DQF)–COSY experiment^{30–32} [see Figure 1(a)]. Some of the naturally occurring amino acids have a unique spin system which can be directly identified. When long aliphatic chains are involved [e.g. lysine (Lys) or proline (Pro)] it might be difficult to obtain the complete proton connectivity. A TOCSY spectrum^{33–36} [see Figure 1(b)] with a long mixing time (60–80 ms) resulting in a magnetization transfer from the HN proton along the whole spin system usually yields the required information. In strongly overlapping cases editing of the proton spectra via the attached carbons will remove most of the problems. This can be done with a heteronuclear multiple quantum coherence (HMQC) experiment^{37–39} [see Figure 1(c)] which leads to direct H,C correlations, or is very efficient via an HMQC experiment with

TOCSY transfer (HMQC–TOCSY)⁴⁰ [see Figure 1(d)]. Both experiments use a BIRD pulse⁴¹ to suppress protons bound to ^{12}C .^{42,43} They have longer relaxation times than those bound to ^{13}C . Their suppression allows a higher repetition rate.

The resonance assignment using both ^1H and ^{13}C is particularly recommended when several similar spin systems occur or proton shifts have a low dispersion, as is probable in linear flexible peptides. Carbon-13 resonances are spread over a larger spectral range than protons. Generally, in HMQC–TOCSY spectra all proton spin systems are well separated and can easily be identified. When even higher resolution of the ^{13}C resonances is required, folding in this dimension is applied.⁴⁴ Another possibility of achieving higher resolution is via pulse sequences for selection and editing of multiplicities, such as HQQC⁴⁵ to select $^{13}\text{CH}_3$ groups [see Figure 1(e)] or DEPT–HMQC^{46,47} [see Figure 1(f)], which results in extremely well-separated spectra.

2.1.2 Connecting Apparently Isolated Spin Systems in Side Chains

Several amino acids have very similar AMXY patterns for their HN, H- α , H- β , and H- β' protons. A full identification of the amino acid requires establishing the connectivity to the rest of the side chain. For example, aromatic amino acids such as phenylalanine (Phe), tyrosine (Tyr), tryptophan (Trp) and histidine (His) can be identified in many cases and distinguished from the very similar AMXY spin system of cysteine via long-range couplings between the β -protons and aromatic protons. It is more efficient to connect these spin systems via heteronuclear long range coupling (HMBC)⁴⁸ [see Figure 1(g)] using the quaternary carbon as a spy looking into both spin systems. Apparently isolated proton spin systems can also be connected via NOE effects [ROESY, see Figure 1(h), or NOESY, see Figure 1(i)]. Caution is required because proximity in space does not always correspond to proximity

Table 1 Overview of the Best Experiments for the Signal Assignment of Peptides

Purpose	Experiment	
	First choice	Second choice
<i>Identification of amino acids</i>		
establishing proton spin systems	TOCSY	COSY
connecting isolated proton spin systems in the side chains	HMBC	NOESY ROESY
proof of α . . . ω connectivity, remove overlap	HMQC–TOCSY	
<i>Sequential assignment</i>		
using heteronuclear long-range coupling	HMBCS	
using NOE effects		NOESY ROESY
<i>Full assignment</i>		
(a) stereospecific assignment using only coupling constants [$^3J(\text{H,H})$, $^3J(\text{C,H})$, $^3J(\text{N,H})$]	PECOSY HMBC HETLOC PECOSY	
using homonuclear coupling constants and NOE ^a		NOESY ROESY
(b) Full side-chain assignment		
aromatic protons	HMBC	NOESY ROESY
methyl groups	HQQC–TOCSY	

^aDoes not lead in all cases to unambiguous assignment. However it is sufficient for restricted systems such as proline.

Figure 1 Pulse sequences of all NMR experiments in this article

according to chemical bonds. Hence, if possible, through-bond connectivity provided by coupling constants is preferred.

Trp and His can also be distinguished from Phe and Tyr by the typical low-frequency shifts of their β -carbon.⁴⁹

2.1.3 Identification via Sequencing

Another way of identifying the spin system of amino acids is the comparison of the known primary sequence with the information obtained from spectral sequencing as described in the following section (see also Figure 2). However, sequencing of proteins²⁹ or peptides in micellar solution may require more sophisticated techniques involving ^{15}N and/or ^{13}C labeling^{50,51} to circumvent problems of overlap and faster relaxation (broad signals).

2.2 Sequential Assignment

Sequential assignment is necessary if not all of the spin systems can be assigned unequivocally or if some amino acids occur several times in the peptide sequence. It simultaneously provides proof of the correct assignment of the spin systems. NOESY⁵² and ROESY^{53–55} experiments both contain sequential information. Dipolar relaxation results in cross peaks from the HN proton of one residue to its own α -proton and to the α -proton of the preceding residue. Using this information the sequence can be obtained in almost all cases. Exceptions only occur when distinct secondary or tertiary structural elements lead to additional long-range HNH- α NOEs. An unambiguous method is the use of HMBC spectra. Long-range coupling leads to signals from the carbonyl of one

Figure 2 Scheme of information for the assignment of resonances resulting from different experiments

residue to the α - and/or β -protons of its own spin system and to the HN, and often also to the α -proton of the following residue. As carbonyl carbons resonate in a small spectral range, selective excitation of the carbonyl carbons via a 270° Gaussian selective pulse is recommended to reduce the spectral range in the ^{13}C dimension and improve its resolution⁵⁶ [HMBCS, see Figure 1(k)].

3 NMR PARAMETERS FOR THE DETERMINATION OF THE SPATIAL STRUCTURE

3.1 Distance Restraints

Distance restraints can be obtained via dipolar relaxation experiments using NOE.^{57,58} The NOE (and the cross-relaxation rate σ) depend on the Larmor frequency and the correlation time of the molecule:

$$\sigma \sim \omega \tau_c \quad (1)$$

Due to their long correlation times, large molecules like proteins exhibit NOEs of -100% , which give rise to intensive positive cross peaks (with respect to the diagonal) in NOESY spectra. For small peptides the NOE is positive (maximum: 50%) but often close to zero (depending on the field strength, the viscosity of the solution, and the molecular size). Only weak NOE cross peaks can be detected. Sometimes positive and negative cross peaks appear in the same spectrum when internal mobility differs in different parts of the molecule. In these cases it is convenient to use the ROE for the determination of proton–proton distances. The ROE is always positive and can therefore be observed even with a cross relaxation σ close to zero ($\tau_c^{-1} \approx \omega$). If the nature of the solvent allows, lowering the temperature to shift the molecular tumbling in the direction of the slow motion limit of NMR spectroscopy ($\tau_c^{-1} \ll \omega$) is also recommended. Low-temperature NOESY spectra have been successfully applied to lipophilic peptides such as antamanide^{59,60} and cyclosporin,¹⁶ and yielded a dramatically improved data set.

For the conversion of the integral values of the observed cross peaks into distances, the isolated two-spin approximation is commonly used. The cross-peak intensities in the initial buildup regime are proportional to the referring distances according to

$$I_1/I_2 = r_1^{-6}/r_2^{-6} \quad (2)$$

The calibration of the distances is achieved by the use of a known distance, e.g., the cross-peak intensity of geminal protons which refers to a distance of 178 pm. Another approach starts with a calibration guess and, after performing a restrained MD calculation, recalibration is done to achieve better agreement between all restraints and calculated distances. This optimal fit is iteratively obtained.

It is important to mention that spin diffusion occurs for long mixing times, especially in the slow motion limit, and distributes the magnetization in the worst case equally over the whole spin system, eliminating the linearity between intensity and distance. A compromise has to be found: the mixing time has to be long enough to observe intense cross peaks but short enough for the system still to be in the linear buildup region of the NOE. Proton–proton distances of small peptides can normally be obtained with mixing times in the range of 100–250 ms. For the determination of buildup curves a number of NOESY or ROESY spectra with different mixing times have to be recorded. Aggregating peptides or peptides in highly viscous solvents have to be treated similarly to large proteins. Spin diffusion can be taken into account by solving the relaxation matrix.⁶¹ A practical approach is the use of the iterative relaxation matrix approach (IRMA)^{62–64} or MARDIGRAS.⁶⁵ For example the lithium complex of cyclosporin A is already aggregated and IRMA was necessary to obtain reliable distances. On the other hand, pure cyclosporin A in CDCl_3 or THF solution can be investigated even at low temperatures without taking spin diffusion into account.

Intensities of ROESY cross peaks depend on the frequency offset of the spin locking field. This has to be taken into account in the form of an offset correction.^{66,67}

$$A(\gamma B_1) = A \sin^2 \theta_k \sin^2 \theta_l \quad (3)$$

$$A_{\text{comp}}(\gamma B_1) = A \sin \theta_k \sin \theta_l \quad (4)$$

Equation (3) describes the modulation in a normal ROESY spectrum, with $\theta_{k,l} = \tan^{-1}(\gamma B_1/\Omega_{k,l})$ and $\Omega_{k,l}$ as the offset of the spins k and l from the transmitter frequency, whereas equation (4) is the analogous expression for a compensated ROESY spectrum⁶⁷ [see Figure 1(l)].

3.2 Measurement of Coupling Constants

Vicinal coupling constants contain supplementary information about the conformation of peptides. They are related to the corresponding dihedral angles via the Karplus equation.^{68,69}

$$^3J = A \cos^2 \Theta + B \cos \Theta + C \quad (5)$$

Parameters are available for a variety of possible homo- and heteronuclear coupling constants in peptides^{70,71} (see Table 2). There are four coupling constants that describe the same dihedral angle ϕ , namely the homonuclear coupling $^3J(\text{HN}, \text{H}-\alpha)$ and the heteronuclear couplings $^3J(\text{C}-\beta, \text{NH})$, $^3J(\text{CO}, \text{NH})$ and $^3J[\text{CO}(i-1), \text{H}-\alpha i]$.⁷² Heteronuclear coupling constants are now easy to obtain even in natural abundance (see below). The χ_1 angle can be described by the

Table 2 *A*, *B* and *C* Parameters for the Karplus Curves of Homonuclear and Heteronuclear Coupling Constants^a

Dihedral angle	Coupling constant	<i>A</i>	<i>B</i>	<i>C</i>
ϕ	$^3J(\text{HN}, \text{H}-\alpha)$	9.4	−1.1	0.4
	$^3J(\text{HN}, \text{H}-\beta)$	6.7	−1.3	1.5 ^b
	$^3J(\text{CO}, \text{NH})$	5.8	−2.7	0.1
	$^3J(\text{C}-\beta, \text{NH})$	4.5	−1.5	−0.2
	$^3J[\text{CO}-i, \text{H}-\alpha(i+1)]$	9.0	−4.4	−0.8
χ_1	$^3J(\text{H}-\alpha, \text{H}-\beta)$	9.5	−1.6	1.9
	$^3J(\text{CO}, \text{H}-\beta)$	6.1	−2.7	1.0

^aBystrov.⁷⁰^bLudvigsen et al.⁷¹

homonuclear coupling $^3J(\text{H}-\alpha, \text{H}-\beta)$ and the heteronuclear coupling constants $^3J(\text{CO}, \text{H}-\beta)$, $^3J(\text{N}, \text{H}-\beta)$ and $^3J(\text{C}-\gamma, \text{H}-\alpha)$.

Constraints for the ψ angle are much more difficult to obtain. Possible vicinal couplings defining the range of this dihedral angle have to contain the peptide nitrogen. The vicinal coupling constants $^3J[\text{N}(i+1), \text{C}-\beta i]$ and $^3J[\text{N}(i+1), \text{H}-\alpha i]$ can only be obtained for ¹⁵N-enriched samples and their range of values is too small to determine the related dihedral angle precisely. Another method of determining restraints for the ψ angle is the use of the one-bond coupling constant $^1J(\text{C}-\alpha, \text{H}-\alpha)$.⁷³ The value of this coupling constant depends on the orientation of both, the ϕ and the ψ angle. The appropriate Karplus curve is:⁷⁴

$$^1J(\text{C}-\alpha, \text{H}-\alpha) = A + B \cos^2(\phi + \delta) + C \cos^2(\psi + \delta) \quad (6)$$

Parameters for this equation have been determined ($A = 138.4$, $B = 13.7$, $C = -5.2$). A slightly different equation has also been derived, but this function is almost identical to the one given here.⁷⁵ The disadvantage of using $^1J(\text{C}-\alpha, \text{H}-\alpha)$ is the relatively small dependence on ψ , as can be seen from the coefficient C , which is about three times smaller than B . But if the ϕ angle is well determined the ψ angle restriction according to equation (6) can be used as a conformational restraint (see below).

The values for the $^3J(\text{HN}, \text{N}-\alpha)$ coupling constants can often be obtained from the HN doublets of the one-dimensional ¹H spectrum recorded with 32K or 64K data points resolution. In cases of small shift dispersion of the HN protons, often occurring when the peptide is very flexible, they have to be extracted from DQF-COSY- or PECOSY spectra [see Figure 1(m)]. Directly reading the coupling constant from the splitting in the antiphase cross peak leads to an overestimated value, due to cancellation in the overlapping region and subsequent shifts of the maxima of the antiphase pattern. The method of Kim and Prestegard⁷⁶ uses a trace of the HN-H- α cross peak phased to the pure absorption mode and to the pure dispersion mode resulting in two splitting values ν_a and ν_d respectively (see Figure 3), from which the exact value of the coupling constant can be calculated according to equation (7).

$$J^6 - \nu_d^2 J^4 + \left(-\frac{9}{4} \nu_a^4 + \frac{3}{2} \nu_a^2 \nu_d^2 + \frac{3}{4} \nu_d^4\right) J^2 + \frac{81}{64} \nu_a^6 - \frac{9}{16} \nu_a^4 \nu_d^2 - \frac{21}{32} \nu_a^2 \nu_d^4 - \frac{1}{16} \nu_d^6 + \frac{\nu_d^8}{64 \nu_a^2} = 0 \quad (7)$$

**Figure 3** Determination of the HN-H- α coupling constant from a COSY spectrum cross peak

The $^3J(\text{H}-\alpha, \text{H}-\beta)$ coupling constants can be measured from the related α, β cross-peak patterns of COSY experiments using the DISCO procedure^{77,78} or by ECOSY,⁷⁹ resulting in simpler cross-peak patterns. A simple alternative to the original ECOSY is PECOSY,⁸⁰ where the second 90° pulse of the normal COSY sequence is replaced by a smaller flip angle (normally a 20–40°) pulse. Transitions connected directly in the term scheme are strongly suppressed. The dispersive diagonal signals are subtracted via a separate reference spectrum. The ECOSY cross peak between two spins *A* and *B* contains the coupling to the third spin (the so-called passive coupling) by an inphase shift of the submultiplet from which the passive coupling constant can be read (see Figure 4). The reader is referred to the literature for further information.²⁴

The determination of the heteronuclear coupling constants requires much more effort. The $^3J(\text{HN}, \text{C}-\beta)$ and $^3J(\text{N}, \text{H}-\beta)$ coupling constants can be measured with the ω_1 -filtered TOCSY (HETLOC)^{81,82} [see Figure 1(n)]. Similar to that mentioned above for the HMQC, a BIRD pulse is used to suppress the proton signals bound to ¹²C. The resulting cross peaks also show an ECOSY type pattern. The signals are separated in the F_1 dimension by the large 1J heteronuclear coupling constant [$^1J(\text{C}, \text{H}) = 140$ Hz for aliphatic carbons or $^1J(\text{N}, \text{H}) = 92$ Hz] so that the small vicinal coupling constant can be measured in F_2 . With this method coupling constants even smaller than the linewidth can be obtained.

Heteronuclear coupling constants to heteronuclei that do not have a proton attached can be obtained by a method introduced by Titman et al.⁸³ and Titman and Keeler.⁸⁴ This procedure is a combination of a slightly modified HMBC [Figure 1(g)] and a homonuclear reference spectrum. If the signals are overlapped in the one-dimensional reference spectrum a z -filtered TOCSY^{83,84} [see Figure 1(o)] can be used instead. The heteronuclear HMBC cross peak, e.g. between a CO carbon and a β -proton, in the F_2 dimension contains all homonuclear couplings of the proton and is additionally modulated by the desired heteronuclear long-range coupling, whereas a corresponding signal of the homonuclear reference spectrum contains only the homonuclear coupling constants. The reference signal is multiplied by the additional modulating term containing a trial heteronuclear coupling constant. The

Figure 4 Determination of the $^3J(\text{H-}\alpha, \text{H-}\beta)$ coupling constants from an α, β cross peak of a PECOY spectrum

shape of this calculated signal is then compared with that of the actually measured HMBC cross peak. With an iterative procedure, varying the value of the heteronuclear coupling constant, the calculated signal can be fitted to the experimental one.

Values for the one-bond $^1J(\text{C-}\alpha, \text{H-}\alpha)$ coupling constants can be measured by simply recording an HMQC experiment without decoupling during acquisition.

3.3 Temperature Coefficients

The chemical shift values of HN protons change with the temperature depending on their orientation to the solvent. One-dimensional spectra at different temperatures (300–330 K) with a stepwidth of 5 K are usually recorded to study this effect. In cases where the amide region is too crowded it is more convenient to use 2D correlation spectra (e.g. TOCSY, COSY). A temperature gradient larger than -3×10^{-3} ppm K^{-1} in DMSO indicates shielding from the solvent which often (but not always!) indicates involvement in internal hydrogen bonds.^{85,86} Also exchange rates of HN protons with deuterium (adding D_2O) can be used for the same purpose; fast exchange then indicates solvent exposure.

4 *cis-trans* ISOMERIZATION

Peptides containing proline or *N*-alkylated amino acids often exhibit *cis-trans* isomerization about the unknown (Xaa)–Pro peptide bond. At room temperature, exchange between these

conformations is normally slow on the NMR timescale (rates of $0.01\text{--}1\text{ s}^{-1}$) and a double signal set can be identified. The relative population is strongly dependent on the primary structure,³ on the solvent, on the temperature, and often also on the concentration. The *cis-trans* isomerism can be proven by coalescence at higher temperatures or by exchange cross peaks in NOESY or ROESY spectra in the slow exchange regime.²³ ROESY spectra are more suitable for this purpose due to the different signs of ROE and exchange peaks. The NOE/ROE cross peak between the two α protons of the *cis* rotamer can be applied for the assignment of *cis* and *trans* conformers. A strong NOE between the Pro δ protons and the H- α of the preceding residue is indicative of the *trans* isomer.

Peptide bonds not involving *N*-alkylated amino acids strongly prefer the *trans* rotamer. A few exceptions have been found including even relatively unconstrained hexapeptides.^{87–89}

5 DIASTEREOTOPIC ASSIGNMENT

A reliable conformational analysis requires assignment of the diastereotopic protons, e.g., the two β -protons of Phe, etc. Without this assignment pseudoatoms for these methylene groups have to be used for structure calculations. In this case, a correction term of $0.9 \text{ \AA}$ has to be added to the upper distance limit. The resulting range of restraints can become so large that there is essentially no remaining restriction.

The assignment of the diastereotopic β -protons in peptides is based on the (reasonable) assumption of only the staggered rotamers of the side-chain dihedral angle χ_1 being populated.^{90,91} The two homonuclear couplings $^3J(\text{H-}\alpha, \text{H-}\beta)$ and $^3J(\text{H-}\alpha, \text{H-}\beta')$ directly yield the amount of the rotamer $\text{P}_{\text{III}}(\chi_1 = +60^\circ)$ assuming a *gauche* ($\pm sc$) coupling constant of 2.6 Hz and a *trans* (*ap*) coupling of 13.6 Hz. The difference between $^3J(\text{H-}\alpha, \text{H-}\beta)$ and $^3J(\text{H-}\alpha, \text{H-}\beta')$ indicates the ratio of $\text{P}_{\text{I}}(\chi_1 = -60^\circ)$ and $\text{P}_{\text{II}}(\chi_1 = 180^\circ)$. With P_{II} dominating, a relatively large coupling of the carbonyl carbon to the β^{proR} -proton is observed, whereas for P_{I} the amide nitrogen atom shows a large coupling to the β^{proS} -proton. The combination of homonuclear and heteronuclear coupling constants is a reliable technique for the assignment of β -protons without stereoselective deuteration (see Table 3).

Often also NOEs can be combined with homonuclear coupling constants.^{92–94} This is the preferred way when the amount of peptide is small but this procedure depends also on the conformation of adjacent bonds and hence may fail.

For the assignment of the β -protons in proline it is normally sufficient to use the H- α –H- β NOEs because the ring structure of proline avoids ambiguities. The shortest distance is always the NOE between the α - and the β^{proS} -proton. The γ - and δ -protons of proline can be assigned in many cases using their NOEs to the β - and α -protons.

6 STRUCTURE CALCULATION

The conformation of a peptide is obtained by using the experimental restraints (NOE-derived distances and *J*-derived bond angles). In the first approximation it is assumed that only one predominant (backbone) conformation exists. If

Table 3 Homonuclear and Heteronuclear Coupling Constants and NOE Values for the Diastereopic Assignment of β -Protons. (–) Denotes a Small Value of the Coupling Constant and (++) a Large One

	Rotamer P _I	Rotamer P _{II}	Rotamer P _{III}
			
χ_1 (deg)	–60	180	+60
$^3J(\text{H-}\alpha, \text{H-}\beta^{\text{proR}})$ (Hz)	13.6	2.6	2.6
$^3J(\text{H-}\alpha, \text{H-}\beta^{\text{proS}})$ (Hz)	2.6	13.6	2.6
$^3J(\text{CO, H-}\beta^{\text{proR}})$ (Hz)	–	++	–
$^3J(\text{CO, H-}\beta^{\text{proS}})$ (Hz)	–	–	++
$d(\text{HN, H-}\beta^{\text{proR}})$ (pm)	260–380	250–380	370–480
$d(\text{HN, H-}\beta^{\text{proS}})$ (pm)	370–440	250–380	260–380
$d(\text{H-}\alpha, \text{H-}\beta^{\text{proR}})$ (pm)	310	255	250
$d(\text{H-}\alpha, \text{H-}\beta^{\text{proS}})$ (pm)	255	310	250

all experimental data are fulfilled and the final structure is energetically reasonable (according to the force field) one has obtained ‘a structural model’. It has still to be proven whether there are alternative models which would also fulfil the data. This is especially critical if only few data are available. Often in the literature there are structures represented that are based on a very limited data set which are impossible to prove or disprove.

If there is no agreement with calculated and experimental parameters and a data set of high quality is available, one has to assume conformational averaging. In particular, when NOEs and J coupling constants are used, conformational averaging is easier to detect, because both ‘parameter-average’ differently. A structural average (e.g. over an MD trajectory) is different from an NOE- or a J -average because they are not linearly dependent on each other.^{28,95}

Averaged conformations may be analyzed by time-dependent NOE or J restraints,^{96–98} by distance geometry calculations, or by ensemble calculations.⁹⁹

The procedure for calculation is described in more detail in *Synthetic Peptides*. However a short outline of the procedure is given here.

6.1 Starting Structure

The easiest way is to build a starting structure manually. It is recommended that the starting point should be far from what is expected and a short high-temperature simulated annealing protocol should then be performed.

To avoid bias, distance geometry calculations can be applied to produce typically 50–100 structures that are refined in four-dimensional and 3D space using the measured distances and J restraints. Recently the use of an additional restraint potential for amide protons involved in hydrogen bonding has been introduced.¹⁰⁰ The structures with the lowest total and the lowest restraint energy are then analyzed. If all structures converge to a single conformation then this one is used as a starting structure in a subsequent simulation including the solvent.

The latter method using distance geometry is preferable to the MD calculations with many different starting structures,

because it is less time consuming and a better conformational sampling is provided. For underdetermined systems, where too few experimental data are available, distance-geometry (DG) calculations will not converge to a single conformation. In these cases MD simulations using a full force field can be applied, but a very careful interpretation is needed because the ‘structure’ depends on the calculated energy, i.e. the force field.

6.2 Restraints

It is now standard to use NOE-derived distances as lower and upper bound restraints. To increase the quality of the determined structures J coupling constants must also be considered as restraints for structure determination, not only (as often can be found) to check the results of an NOE-based calculation.

For a specific J coupling constant up to four solutions exist. Hence, when using J coupling constants as restraints the full Karplus curve has to be programmed to allow the molecule to get all four solutions in an MD run.¹⁰¹ The energy penalty function is analogous to that commonly used for NOEs

$$E_J = \sum k(J_{\text{theo}} - J_{\text{exp}})^2 \quad (8)$$

where J_{theo} = theoretical J value according to the actual dihedral angle in the trajectory, J_{exp} = experimental J value, and k is a type of force constant to adjust the restraint. By this procedure several different coupling constants can also be used to describe a single bond angle,^{102,103} which results in a reduced number of possible minima (see Figure 5).

6.3 Solvents

The relatively large surface-to-core ratio of small compounds such as peptides leads to a strong dependence of their conformation on the surrounding solvent. Experimental restraints can be used to mimic solvent effects; however it is still very problematic to perform calculations without explicit solvent. To reduce artifacts from charged groups a scaling down of

Figure 5 Potential energy of the coupling constant penalty term for coupling constants fitting a ϕ angle of $+60^\circ$

charges of HN protons according to the measured temperature dependence¹⁰⁴ or a higher pK have also been used. However we have shown that only explicit solvents yield reasonable results.^{105,106} There are force fields available for H₂O, CCl₄, CDCl₃, DMSO, CH₃CN, CH₃OH, CF₃CH₂OH, and the calculation should be done close to the experimental conditions. The starting structure is placed in a box of solvent molecules and equilibrated. A MD simulation using NOEs and J coupling constants of about 100–150 ps is calculated. It is recommended to use another 30–150 ps of free dynamics (without any experimental restraints) in the solvent to check if the structure is stable and reasonable.

When the NMR measurements have been performed in SDS or DMPC a two-phase box¹⁰⁷ can be used. It contains a mixture of CCl₄ and water, mimicking an anisotropic membrane surrounding. A good example for the application of this system is the bradykinin antagonist HOE 140.¹² NMR measurements in isotropic solvents like water or DMSO showed that this molecule is highly flexible (random coil). Applying a combined approach of NMR measurements in SDS micelles and MD simulations in this two-phase box, the conformation and its orientation at the phase interface could be determined.

6.4 Flexibility and Exchange

The above-mentioned simulation techniques result only in structures that fulfill all measured data if the considered molecule strongly populates one single conformation under the conditions of the measurement. In the case of nonagreement

(see above) or other good reasons to assume conformational averaging due to multiple conformations in fast equilibrium, other approaches have to be applied. There exists no method to date that can handle more than just a few rapidly interconverting conformations. The treatment of systems with just a few conformers can be performed with MD calculations using time-dependent NOEs and J coupling constants as restraints.^{96–98} This method takes into account that the measured values may be averaged for different conformations which interconvert rapidly on the NMR timescale. Recently a second approach for the determination of peptide structures for molecules with more than one conformation has been introduced. Distance geometry calculations with an ensemble of low-energy structures using the ensemble averages for the distance- and dihedral-restraint penalty functions result in a few different families of conformations.^{99,108}

7 CONFORMATIONAL FLEXIBILITY

Conformational averaging can be identified via the analysis of NOE/ROE data and J coupling constants. Values for the homonuclear $^3J(\text{HN}, \text{H-}\alpha)$ or $^3J(\text{H-}\alpha, \text{H-}\beta)$ coupling constants of about 7 Hz indicate fast averaging of the ϕ and the χ_1 angles respectively. The appearance of rigid secondary structure elements like β -turns or α -helices is accompanied by a characteristic pattern of HN–HN and HN–H- α NOEs. Together with the values of related coupling constants the type of the turns ($\beta\text{I}, \beta\text{II}, \dots$)¹⁰⁹ or helices can be determined. The occurrence of all sequential and intraresidual HN–H- α NOEs and the absence of medium- or long-range NOEs is generally an indicator of a random coil conformation.

Proof of the flexibility of a molecule under the experimental conditions can be obtained via the analysis of relaxation data. A full analysis is not necessary for small, linear peptides. It is sufficient to determine the ^{13}C T_1 relaxation times using the fast inversion–recovery experiment.¹¹⁰ The determined T_1 relaxation parameters depend on the correlation time τ_c of the CH_{*n*} groups.⁵⁸ This relationship is not unequivocal; two possible solutions can be obtained. For small peptides the shorter τ_c of the two values is normally the true one, but a comparison of the measurements at different field strengths results in a single solution (see Figure 6). A comparison of the determined T_1 values for the α -carbons leading to correlation times of around 0.5 ns for peptides¹¹¹ hints at a uniform mobility for the whole peptide. If the T_1 relaxation times differ some domains are considered to be more flexible than others. The dynamics of side-chain motions can also be detected in this way, as has been shown for the dynamics of Pro side chains in antamanide examined via the T_1 relaxation times of the C- γ protons.^{112,113}

If there are hints for conformational flexibility as normally occurs in small, linear peptides there are several possibilities of influencing the equilibrium or the exchange rates. The easiest method is just to perform the NMR experiments at lower temperature to slow down the correlation times of the molecule and thereby the exchange rate between the conformers. If the temperature is low enough possible interconverting conformations may show discrete sets of signals. But so far restricted rotations about ϕ, ψ angles in noncyclic peptides have never been observed. Suitable solvents are CD₃OD, TFE, CDCl₃, or cryomixtures like DMSO/H₂O (80:20). At a

Figure 6 Plot of the T_1 relaxation time versus the correlation time τ_c for different field strengths: 250 MHz, solid line; 500 MHz, broken line

temperature of 243 K the latter solvent is isodielectric with water at 295 K,⁶ but leads to increased NOEs⁷ due to the lower viscosity. Sometimes simply a change from one solvent to another will shift the equilibrium observed for *cis-trans* conformers about peptide bonds because of the different polarity or specific solvation effects. Recently a distinct flip of the whole peptide bond about adjacent bonds (ϕ, ψ), a process which is often found in cyclic peptides,^{114–116} was induced in the cyclic peptide hymenistatin when changing the solvent from CDCl_3 to DMSO. A different solvation of the amide bond in the two conformations can explain this difference.¹¹⁷ Cyclosporin A, for example, exists in chloroform in a single conformation,^{15–17} whereas in CD_3OD four distinct sets of signals can be detected.¹⁹ A rather drastic change occurs in the measurement in anisotropic, membrane-mimicking solvents (SDS, DMPC), which represents a more realistic environment for peptides naturally occurring in membrane surroundings.

8 CONCLUSION

The high flexibility, the high surface-to-core ratio, the relatively small number of restraints, and the strong polar nature of peptides, all make reliable peptide conformational analysis still a difficult task, which requires spectra of good quality, a set of designed pulse sequences, careful extraction of parameters, and critical and competent calculational procedures; otherwise 'structures' remain 'pictures' of fictitious character.

1 INTRODUCTION

Complex oligosaccharides and polysaccharides are composed of a wide variety of different monosaccharides in different linkages. They are not involved as energy sources in metabolism but should be considered rather as 'informational macromolecules' encoding information which is generally important in intercellular communication. The information which they store is decoded by interaction with specific binding proteins known as lectins.¹ The cell surface oligosaccharides of membrane glycoproteins and glycolipids have been implicated in such important biological functions as inflammation² and cellular differentiation.³ The cell surface polysaccharides of bacteria, including lipopolysaccharides, capsular polysaccharides, and other cell wall polysaccharides are implicated in bacterial adhesion and coaggregation.^{4,5} Two different aspects of the structure are important to an understanding of the biology of these interactions. First, one must determine the covalent chemical structure of complex oligosaccharides and polysaccharides including the absolute configuration of the constituent monosaccharides. Secondly, one must also determine their three-dimensional folding and their conformation. If they do not adopt a single conformation but rather exist in multiple conformations which exchange, then one must also determine the dynamics of the conformational exchange. This knowledge will make a major contribution to our understanding the interactions of complex oligosaccharides with lectins. High-resolution NMR spectroscopy has been important in all three facets of the structure of complex oligosaccharides and polysaccharides.

2 COVALENT STRUCTURE DETERMINATION

Determination of the covalent structure of a complex oligosaccharide or polysaccharide is not so simple as determination of a peptide sequence or of a nucleotide sequence. With the possibility of two sugar ring forms (furanoside or pyranoside) and of two anomeric forms (α and β) as well as multiple linkage positions, much more detailed information is required for a description of the structure of a complex oligosaccharide which often includes branching. At present

there is no single established method for structure determination and many different methods involving enzymatic digestion, chemical degradation, and methylation analysis are used for various problems. The catalog of available *endo*- and *exo*-glycosidases is inadequate and the outcome of chemical reactions involving sugars is notoriously unpredictable. These facts contribute to the attractiveness of instrumental methods such as mass spectrometry and NMR spectroscopy which require minimal chemistry.

2.1 Proton NMR Spectroscopy

The first major contribution of high-resolution ^1H NMR spectroscopy to this problem was the structural reporter group method which became useful with the introduction of high-field superconducting spectrometers operating at 360 MHz. An oligosaccharide or polysaccharide in the quantity range of 100 nmol to 1 μmol is dissolved in D_2O and a ^1H spectrum is recorded with chemical shifts referred to DSS.^{6,7} In this method, which was first used in glycopeptides and was later extended to glycolipids in DMSO solution, certain well-resolved resonances can often be recognized in one-dimensional spectra. For example the anomeric region at ca. 4.4–5.4 ppm usually contains resonances of anomeric protons most of which are isolated (see *Carbohydrates and Glycoconjugates*). Accurately measured values of the chemical shift can be combined with the multiplet splitting to characterize the oligosaccharide or polysaccharide. Other structural reporter resonances which contribute to the fingerprint include methyl doublets near 1.3–1.5 ppm typical of 6-deoxyhexoses and methyl singlets around 2.0 ppm characteristic of *N*- or *O*-acetyl methyl groups. Methylene resonances of 3-deoxy sugars can be found between 1.8 and 2.3 ppm. But many overlapping resonances of the methine protons between 3.5 and 4.0 ppm are unresolved and contribute minimal information. The chemical shifts and multiplet structures of the isolated structural reporter resonances can be used to characterize the oligosaccharide or polysaccharide, since no two distinct structures have ever been found to have the same NMR spectrum.

Although the structural reporter method has been used primarily for *N*-linked glycopeptides and glycolipids, it can be used on any oligosaccharide or polysaccharide for which a reference library of closely related structures is available (see *Carbohydrates and Glycoconjugates*). The method has also been used extensively for the oligosaccharide alditols isolated from the alkaline borohydride degradation of mucin glycoproteins.^{8–10} In polysaccharides with a repeating subunit, only the structural reporter resonances of the repeat unit are observed and the spectrum resembles that of an oligosaccharide without a reducing terminal. The method works well in any system of closely related bacterial polysaccharides.¹¹ Although the structural reporter method has been generally associated with ^1H NMR spectroscopy, a very similar approach has been used in the ^{13}C NMR of bacterial polysaccharides as will be described below. The structural reporter method for ^1H spectra is fast (~ 30 min) requiring less spectrometer time than other NMR methods and is comparatively sensitive yielding at least some information on samples as small as 20–100 nmol.

A complete assignment of all the proton signals is more difficult, but it provides much more information

on the structure of a polysaccharide for which there are no available spectra for closely similar compounds. A complete assignment of the ^1H spectrum can in principle be established by spin correlation since each sugar ring forms a chain of scalar coupled spins. While correlation by scalar coupling was originally done by spin decoupling, usually by difference methods, two-dimensional methods such as COSY are generally preferred for modern instrumentation. The experiment is usually performed in a phase-sensitive mode with a double quantum filter.^{11,12} Spin correlation is started at the anomeric proton resonance or at some other structural reporter resonance such as a methyl doublet of a 6-deoxyhexose. Correlation through the entire spin system by COSY can be augmented by 2D HOHAHA or TOCSY which is especially valuable for resonances which are close in chemical shift, giving rise to COSY cross peaks close to the diagonal.¹³ From these 2D COSY and TOCSY spectra, one can extract the homonuclear coupling constants which are very useful in assigning the stereochemistry of the sugar pyranoside residue. Two vicinally coupled protons which are axial make a dihedral angle of 180° implying a large coupling constant which is observed in practice to range from 7–11 Hz, whereas any coupling involving equatorial protons exhibits a small *gauche* coupling constant ranging in practice from 0.5–3 Hz (see *Vicinal Coupling Constants and Conformation of Biomolecules*). Hence these data reveal whether substituents are axial or equatorial, providing the anomeric configuration of the glycosidic linkage as well as the identity of the sugar residue. The identities of the monosaccharides are then to be confirmed by carbohydrate analysis by a method such as HPLC.

Two common difficulties arise which may prevent the above scheme from providing a successful assignment of the ^1H spectrum. The first problem is strong coupling which is all too common in the crowded 3.4–4.4 ppm region of the carbohydrate spectrum. It arises when the chemical shifts of two resonances which are coupled are separated by an amount which is not large compared with the coupling constant. Homonuclear two-dimensional TOCSY or HOHAHA spectroscopy can be used to obtain cross peaks which are well removed from the diagonal in many cases. But if the difference in chemical shift is less than twice the coupling constant, the multiplet shape cannot be extracted interfering with the assignment of stereochemistry by homonuclear coupling, $^3J(\text{H,H})$. In this case, heteronuclear NMR methods involving ^{13}C resolution are required, as will be discussed below. A second problem in spin correlation about the ring arises for very small values of $^3J(\text{H,H})$ associated with some *gauche* protons.

NOESY correlations can often be used to correlate such *gauche* protons since they are close in space. A hybrid homonuclear method combining TOCSY with ROESY or NOESY may be useful in such cases and long-range heteronuclear coupling correlation can also be useful as will be described below (see *Carbohydrates and Glycoconjugates*).

Although the scheme outlined above for spin correlation can be used to assign all proton resonances in a ring and to identify the sugar residues and their anomeric configuration, it does not provide the sequence of residues or their linkage and branching. For this purpose, homonuclear spin correlation is not informative and correlation through space by NOESY can be employed. The anomeric proton of one residue is often

close to the aglycone proton directly across the glycosidic linkage, giving rise to NOESY cross peaks which identify the linkage.^{13,14} Unfortunately this proximity depends on the conformation of the glycosidic linkage and many exceptions are observed in which a large NOE is seen between the anomeric proton resonance and that of the proton adjacent to the linkage position. This situation arises most often when the adjacent proton is equatorial.^{11,13} Although the NOESY data can be useful for the assignment of oligosaccharide sequences, the information on the linkage position is not definitive unless the conformation is known, which is usually not the case for a completely new polysaccharide of unknown structure. Thus the linkage position must be confirmed by some other type of data, such as methylation analysis or long-range heteronuclear correlation to be described below.

Observation of NOESY in oligosaccharides and polysaccharides is complicated by difficulties arising from a dependence on the rotational correlation time. NOE is positive for small molecules and negative for larger ones such as proteins and DNA duplexes.¹⁵ (See *Nuclear Overhauser Effect*.) For intermediate sized molecules having a rotational correlation time τ_c approximately equal to the reciprocal of the spectrometer frequency ω , the NOE disappears altogether. This is approximately the case for a tetrasaccharide at 500 MHz. One solution to this problem is to change the viscosity of the solution, and thus the τ_c , by changing the sample probe temperature¹⁶ or the viscosity of the solvent by the addition of a viscous cosolvent such as DMSO.^{17,18} If it is not desirable to alter the solvent conditions, one can resort to NOE in the rotating frame for which NOEs are positive for all rotational correlation times (see *ROESY* and *Carbohydrates and Glycoconjugates*.) One difficulty with this experiment, which is known as ROESY, is that one must be careful to account for magnetization transfer by the HOHAHA mechanism which leads to cross peaks of the opposite sign and which may cancel ROESY peaks.

The observation of a NOE in polysaccharides is usually straightforward since it is commonly large and negative. Wide variations in flexibility are observed among polysaccharides depending strongly on the linkages. Thus wide variations of linewidth are observed, but generally the NOE is negative.¹¹ The dynamics of the internal motion in polysaccharides is a complex topic which will be addressed below.

2.2 Carbon-13 NMR Spectroscopy

The ^{13}C spectra of carbohydrates generally show much better chemical shift dispersion than do the ^1H spectra. In D_2O solution referenced to DSS, the anomeric signals are dispersed between 95 and 110 ppm and methyl carbon resonances are observed at 15–25 ppm. Since the signals corresponding to the methine carbon atoms of the sugar ring are spread over a much wider spectral region (between 55 and 85 ppm) than are the corresponding signals in the ^1H spectrum, there is only a moderate amount of overlap of the signals even at the low fields typical of iron core magnet NMR spectrometers (20–25 MHz carbon ^{13}C frequency). With the introduction of Fourier transform ^{13}C spectroscopy in the 1970s, the spectra of many carbohydrates were recorded, revealing both the promise and some of the difficulties with this type of spectroscopy. A major problem arises from the low sensitivity associated with the direct observation of ^{13}C in natural abundance, especially

with low magnetic field strength spectrometers. Although the requirement for sample sizes of 20–50 μmol severely limited applications to oligosaccharides from eukaryotic glycopeptides and glycolipids, bacterial polysaccharides are often available in such quantities and spectra were reported for a number of bacterial polysaccharides such as the *O*-antigen chains of lipopolysaccharides (LPS), capsular polysaccharides, and other bacterial cell wall polysaccharides.^{19–21} A second problem with these early studies of ^{13}C NMR spectra of carbohydrates was the lack of a simple method for the rigorous assignment of ^{13}C signals analogous to the $^3J(\text{H},\text{H})$ correlation method described above for the assignment of ^1H spectra. In the absence of a correlation method, the only data upon which to base resonance assignments were ^{13}C chemical shifts and extensive sets of rules for 'glycosylation shifts' were developed.^{22,23} Recently more sophisticated computer-based schemes for this type of correlation have been developed for complex oligosaccharides.^{24–26} Although the large chemical shift dispersion of ^{13}C spectra leads to well-resolved spectra, the large effects complicate any rational scheme for assignment based on regular differences in chemical shifts. This situation has led to many revisions of the spectral assignments of the ^{13}C spectra of complex carbohydrates as more rigorous correlation-based methods for assignment were introduced. These methods include specific ^{13}C incorporation by chemical synthesis,²⁷ DEPT methods which count the protons bonded to a particular carbon atom,²⁸ or comparison of chemical shifts in D_2O and H_2O solution (DIS).²⁹ In spite of the difficulties in obtaining reliable ^{13}C resonance assignments in these early ^{13}C studies, the data proved to be immensely useful in studies of bacterial polysaccharide structure.^{19,20}

Major advances in ^{13}C NMR spectroscopy of polysaccharides have resulted from the more common use of correlation methods which follow chemical bonds. Rigorous assignment of the ^{13}C spectrum can be derived from the ^1H assignment by one-bond C–H coupling correlation. While such a correlation is not very practical for ^{13}C detection in macromolecules, the recent introduction of inverse detection or ^1H -detected ^{13}C spectroscopy has greatly increased the utility of this approach. Not only is the sensitivity of ^1H -detected ^{13}C spectra greatly improved, but it also gives the ^1H spectrum the higher resolution of the detected dimension where it is most needed. In a convenient implementation called HMQC³⁰ the rather crowded ^1H spectrum is resolved in the F_1 dimension by the excellent dispersion of the ^{13}C dimension. This spreads out the resonances that would otherwise overlap in the ^1H spectrum and also provides a scheme for the assignment of the ^{13}C resonances once a rigorous assignment of the ^1H spectrum is derived from homonuclear spin correlation as described above.³¹ Another advantage of HMQC arises in the case of strongly coupled ^1H resonances, which are often resolved by the difference in ^{13}C chemical shift. The large value of $^1J(\text{C},\text{H})$ ($\sim 140\text{ Hz}$) removes the strong coupling for natural abundance samples in which there is only one ^{13}C atom in the average sugar ring.¹¹ In the absence of strong coupling, the correct homonuclear multiplet shape can be deduced as required for the assignment of the stereochemistry of the pyranoside ring and identification of the sugar. With hybrid methods such as coupled HMQC–COSY, one can assign the correct multiplet shape and chemical shift even in cases for which the ^1H resonances exactly overlap.³² The combination of ^1H homonuclear correlation and ^1H -detected ^{13}C correlation enables a complete

assignment of both spectra for complex carbohydrates which are available in quantities of about 1 μmol . This is reasonable for bacterial polysaccharides, but may not be suitable for glycopeptides or glycolipids from eukaryotes which are often not available in such large quantities.

Another important extension of these heteronuclear methods is long-range correlation of ^1H with ^{13}C over two and three bonds by the method popularly known as HMBC.³³ The pulse sequence is similar to that used for HMQC but it involves longer delays to allow antiphase magnetization to develop over the smaller coupling. In this experiment, there is a reduction in sensitivity due to the long delays (30–50 ms) which are required and if T_2 is not much longer than the delays, substantial signal is lost. Particularly for polysaccharide samples with wide lines, this experiment is less sensitive than HMQC and can require as much as 10 μmol of sample depending on the linewidth. HMBC spectra provide valuable confirmation of ^1H and ^{13}C resonance assignments through correlation within the sugar ring, and also complete assignments for cases in which vicinal homonuclear coupling constants are too small to provide correlation.¹¹ But the main function of HMBC spectra is correlation across the glycosidic linkage.³¹ This allows assignment of the glycosidic linkage in a rigorous way which follows the chemical bonds. This method has found a number of recent applications for determining glycosidic linkages in bacterial polysaccharides.¹¹ In favorable cases, this information can take the place of data from methylation analysis and a complete structure of a polysaccharide can be determined essentially by NMR methods with very little ancillary data.

3 CONFORMATION AND DYNAMICS

The question of the three-dimensional conformation of complex oligosaccharides and polysaccharides is distinct from the primary or covalent structure. A truly detailed understanding of the conformation and dynamics requires contributions from a number of techniques, but at the present time data from NMR spectroscopy have made the most significant contributions to the solution of this problem. Computer molecular modeling is generally essential to the satisfactory interpretation of the experimental NMR data.³⁴ It seems likely that contributions from other experimental biophysical methods such as X-ray crystallography and fluorescence spectroscopy can be expected to increase as the importance of oligosaccharide–lectin interactions becomes more apparent.³⁵

An early contribution of NMR data to oligosaccharide conformation was the homonuclear $^3J(\text{H},\text{H})$ values which are especially useful for determining the puckering of the pyranoside rings of sugars. Since the six-membered pyranoside rings generally assume defined chairs, their $^3J(\text{H},\text{H})$ values are either large (7–11 Hz) for coupling between axial protons or small (0–3 Hz) for coupling involving equatorial protons, as is described above in connection with the assignment of ring stereochemistry. For furanosides, the pucker is much more complicated, with the five-membered rings adopting envelope conformations in rapid exchange. Measurements of $^3J(\text{H},\text{H})$ for furanosides have been useful in determining the relative contributions from the various envelope conformations which are important in DNA and RNA conformation.³⁶

(See *Vicinal Coupling Constants and Conformation of Biomolecules*.) A combination of empirical and ab initio calculations has been used to model the furanoside rings and to fit the $^3J(\text{H,H})$ data to the model.

For oligosaccharides composed of relatively rigid pyranoside rings, the glycosidic dihedral angles describe the conformation and dynamics of the polysaccharide.³⁷ Homonuclear coupling data are uninformative regarding the relative conformation of the rings with respect to each other and much more information on oligosaccharide and polysaccharide conformation has been derived from ^1H NOE data which report on distances through space.¹⁵ (See *Nuclear Overhauser Effect*.) The strategy is similar to that used in the determination of protein structure in solution by NMR methods which relies heavily on computer modeling methods for an interpretation of the NMR data (See *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). The earliest studies of oligosaccharide conformation were performed on chemically synthesized models of blood group oligosaccharides in which steady-state NOEs were interpreted qualitatively.³⁸ Models were built with a simple empirical energy function and the NOE data were interpreted qualitatively to confirm these models. This method has also been used in bacterial polysaccharides.^{39,40}

A more quantitative method for incorporating the NOE data into molecular modeling schemes follows methods often used in the interpretation of NMR data of proteins in which experimental distance constraints are derived from the NOE data. The distance constraints, which are most commonly derived from the 'isolated spin pair approximation', are treated as pseudo energy terms in the modeling to force a conformation which is consistent with the experimental NOE data (see *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). Choe et al.⁴¹ have used NOE constraints to study the core oligosaccharide of the glycosamino glycans and Scarsdale et al.⁴² have described an application to gangliosides. Homans and Forster⁴³ have also outlined a detailed method for restrained molecular dynamics for oligosaccharides.

A slightly different approach to the quantitative evaluation of NOE data for modeling of oligosaccharides is spin matrix analysis. In this method a molecular model is built and interactions among all the ^1H spins are treated to include three spin effects and spin diffusion (see *Protein Structures: Relaxation Matrix Refinement*). The model is then adjusted to determine whether any conformation can be found for which all the simulated NOE data agree with experiment. This method was first introduced by Brisson and Carver⁴⁴ for steady-state NOE in glycopeptides. The matrix method for oligosaccharides was later extended to transient two-dimensional NOESY data which are technically more convenient.⁴⁵ The spin matrix method has been adapted to include quantitative interpretation of rotating frame or ROESY data.⁴⁶

An inherent problem with both methods outlined above for the quantitative interpretation of NOE data for oligosaccharides is that they ignore internal motion. The matrix method begins with the assumption of a simple isotropically rotating rigid model and the restrained molecular modeling methods are generally assumed to converge to a single conformation. Careful analysis of the results of either method can be used to

test for consistency of a single rigid model with the experimental data, but it is difficult to incorporate internal motion into a quantitative NOESY calculation. The question of the flexibility of complex oligosaccharides is important and remains somewhat controversial.^{47,48} Certainly, the relatively narrow lines observed in NMR spectra of polysaccharides (2–15 Hz) having molecular weights as high as 100 kDa suggest that there must be some type of flexibility. One possible interpretation is that certain types of oligosaccharides, such as the blood group epitopes, do assume relatively rigid conformations, while other sugar linkages are flexible, providing structural 'hinges'.^{34,48}

One approach to the interpretation of NOE in the presence of internal motion is to assume that the molecular modeling results are correct, assign statistical weights to the minimum energy conformations, and then calculate average NOE. Under the assumption that the rate of conformational exchange is fast compared with T_1 but slow compared with the overall τ_c of the oligosaccharide, one may average the values of the spin matrix elements and then solve the problem.^{45,48} Unfortunately it is not known whether this assumption about the kinetics of conformational exchange is correct.

The uncertainty about the details of the conformational dynamics of polysaccharides suggests that additional types of experimental information are needed. The interpretation of NOESY data for a system with internal motion can be quite complex since motion can modulate not only the orientation of ^1H – ^1H vectors but also the distances between protons. It has been recognized for many years that heteronuclear coupling $^3J(\text{C,H})$ values could be used to correlate with dihedral angles (see *Vicinal Coupling Constants and Conformation of Biomolecules*). Interpretation of coupling data such as $^3J(\text{C,H})$ in an oligosaccharide with internal motion is much simpler than NOE since the motion is almost certainly fast compared with the timescale of the interaction (ms). But it has proven to be technically very difficult to measure these coupling constants for macromolecules with ^{13}C in natural abundance. Data were first reported from 1D ^{13}C spectra and ^1H spectra of oligosaccharides synthesized with specific ^{13}C enrichment.²⁷ More recently, long-range heteronuclear coupling constants have been measured in natural abundance by ^{13}C -detected ^1H spin echo methods.⁴⁹ But the low sensitivity of ^{13}C -detected methods presents a serious limitation and this method requires a resolved ^1H spectrum which is a rarity in complex carbohydrates. The improved sensitivity of ^1H detection, which has been described above for long-range ^{13}C – ^1H correlation, provides a method for encoding values of $^3J(\text{C,H})$.⁵⁰ Several one-dimensional versions of ^1H -detected $^3J(\text{C,H})$ have been demonstrated in disaccharides and trisaccharides by Poppe and van Halbeek.⁵¹ In spite of the improved sensitivity, cancellation of the antiphase components of heteronuclear doublets hampers accurate measurements for macromolecules. When the linewidths are comparable to the values of the coupling constants (1–8 Hz), the latter cannot be accurately measured due to antiphase cancellation. In the ECOSY method of Montelione et al.,⁵² large one-bond coupling to resolve the long-range coupling removes the problem of overlap making it possible to measure accurately coupling constants much smaller than the linewidth.⁵³ (See *Coupling Constants Determined by ECOSY*.) This approach has been used in carbohydrates in natural abundance with ^{13}C selective filters,⁵⁴ and in polysaccharides with uniform ^{13}C enrichment.⁵⁵

The question of internal motion in complex polysaccharides can also be addressed by spin relaxation methods in which $J(\omega)$, the spectral density, is sampled at a number of different frequencies to measure the different types of motion which contribute to nuclear relaxation. Measurements of different relaxation rates, T_1 , T_2 , $T_{1\rho}$, and NOE of ^{15}N or ^{13}C can be combined in order to provide this information.

1 INTRODUCTION

The present article describes the results from studies of protein hydration by way of nuclear Overhauser effects (NOEs) observed between the water signal and the proton resonances of the protein (see also *Dynamics of Water in Biological Systems: Inferences from Relaxometry*). Intermolecular NOEs between peptides and hydration water were already reported in the 1970s.¹ However, their sensitivity with respect to on the dynamics of protein hydration was only realized almost 20 years later.²

The NOE provides a mechanism for magnetization transfer that arises from the dipole–dipole interaction between the nuclear magnetic moments of spins that are close in space. The strength of the interaction decays rapidly with increasing internuclear separation, so that, in practice, sizeable NOEs are observable only between protons that are closer than about 5 Å. The short-range nature of the NOE interaction thus ensures that of all the water in the solution, only hydration water from the first shell of hydration around a protein is detected by the NOE experiment.

In principle, NOEs observed between the protons of hydration water molecules and protein protons provide distance constraints that can be used to complement a protein structure with the coordinates of hydration water molecules (see *Biological Macromolecules: Structure Determination in Solution; Distance Geometry*, and *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*).^{3,4} In practice, this task is complicated by the fact that only a single signal is observed for all water protons in the ¹H NMR spectrum of an aqueous protein solution. The degeneracy of the proton chemical shifts of water molecules in hydration sites and water in the bulk of the solution is a consequence of the rapid chemical exchange of water molecules (or at least their protons) between these two different chemical environments with rates beyond about 1000 s⁻¹.⁵ Therefore, the distinction between different hydration water molecules requires the accurate knowledge of the three-dimensional (3D) structure of the protein, which makes it possible to assess the number of water molecules required to explain all the experimentally observed water–protein NOEs. Furthermore, the three-dimensional structure is also needed to distinguish NOEs with hydration water from NOEs with labile

protein protons, which appear at the chemical shift of the water resonance because of rapid exchange with the water.

Water–protein NOEs have been found to occur with positive and negative signs. A negative water–protein cross peak is observed in NOESY experiments, when the motional reorientation of the vector connecting a water proton with a protein proton occurs in a time span shorter than the angular Larmor frequency. The present article discusses why this motional reorientation is best interpreted in terms of a diffusion model where positive and negative signs of the NOESY cross peaks indicate that the residence times of the hydration waters are, respectively, longer or shorter than about 0.5 ns with respect to the protons of the protein. Negative cross peaks are usually observed for hydration water on protein surfaces, whereas water molecules in interior protein cavities give rise to positive cross peaks with the protein protons.

Overall, NMR studies of protein hydration identify the hydrated protein protons and convey information on the lifetime of hydration. In contrast, X-ray diffraction studies of proteins in single crystals detect water molecules by their statistical probability of being at defined positions and are far less sensitive to their residence times.

2 NMR EXPERIMENTS

The water signal in the ¹H NMR spectrum of an aqueous protein solution is typically about 10 000 times more intense than the individual proton signals of the protein. This dynamic range exceeds by far what modern NMR spectrometers can sensibly handle and calls for some method of water suppression.

Saturation of the water signal by selective irradiation is the most frequently used technique of water suppression in homonuclear NMR experiments. Water suppression by selective preirradiation is also commonly used with the two-dimensional NOESY experiment, which is the standard experiment for the detection and assignment of NOEs in proteins (see *Biological Macromolecules: Structure Determination in Solution, Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*, and *Water Signal Suppression in NMR of Biomolecules*). However, no cross peaks can be detected between the resonances of the water and the protein in this experiment, since the presaturation of the water signal eliminates the water magnetization before it can be transferred to the protein resonances via NOE during the mixing period. The result is an excitation profile that is uniform along the ω_2 dimension, but contains a bleached region along the ω_1 frequency axis at the frequency of the water signal [Figure 1(a)]. In principle, cross peaks between protein resonances in ω_1 and the water resonance in ω_2 are still present in this experiment, but they are obscured by the strong band of t_1 noise from the residual water signal.

Intermolecular water–protein cross peaks are reliably detected in two-dimensional NOESY experiments using an excitation profile that is uniform along the ω_1 dimension and zero at the water frequency along the ω_2 frequency axis [Figure 1(b)]. Such an excitation profile is obtained if the water signal is suppressed only before the detection period t_2 , but not before the evolution period t_1 . In this experiment, the water magnetization is fully excited, transferred to protein spins during the

Figure 1 Pulse sequences for the detection of water–protein NOEs. The resulting excitation profiles are plotted alongside the schematic two-dimensional spectra. The position of the diagonal is indicated by a straight line, a wavy line indicates the band of t_1 noise from the incompletely suppressed water signal, and arrows identify the cross-sections containing the water–protein cross peaks. The phases indicated with the pulses are for a single transient of the phase cycle only. (a) NOESY sequence with suppression of the water signal by selective presaturation. The water–protein cross peaks at the ω_2 frequency of the water resonance are obscured by the t_1 noise of the residual water signal, and there are no cross peaks at the ω_1 frequency of the water resonance. (b) NOESY sequence with spin lock (SL) pulses for water suppression. Water–protein NOEs are observed in the cross-section at the ω_1 frequency of the water resonance

mixing time τ_m , and destroyed immediately before the detection of the FID. The tricky part in the experiment is the water suppression between the mixing time τ_m and the detection period, which needs to be achieved in as short a time period as possible to minimize the relaxation of the magnetization before detection. Different water suppression techniques have been devised in this context, which, unlike saturation of the water signal by selective irradiation, achieve water suppression within a few milliseconds (see **Water Signal Suppression in NMR of Biomolecules**).

Figure 1(b) presents as an example a pulse sequence where the water magnetization is suppressed by two short spin lock pulses before data acquisition.⁶ The phase of the first spin lock pulse is shifted by 90° with respect to the phases of the preceding 90° pulse and the following spin lock pulse. The spin lock pulses have the property of defocusing any magnetization vertical to the spin lock axis, but retaining magnetization of the same phase as the spin lock axis. With the phases indicated in Figure 1(b), the first spin lock pulse selects the desired y magnetization generated by the previous 90_x° pulse. During the following short delay τ , the proton magnetizations precess toward the x axis with a speed depending on their frequency difference Ω with respect to the carrier frequency. The subsequent spin lock pulse selects the x magnetization and defocuses the y magnetization. The resulting excitation profile is given by $\sin(\Omega\tau)$. With the carrier frequency at the frequency of the water resonance, the null of the excitation profile is at the water frequency [Figure 1(b)].

Spin lock pulses and other water suppression schemes have similarly been used in further experiments designed for the detection of water–protein NOEs. These include ROESY,⁷ homonuclear 3D NOESY–TOCSY and 3D ROESY–TOCSY,⁶ and heteronuclear 3D NMR experiments.^{8–10} Of these, the ROESY experiment presents valuable information on the water–protein interaction that is complementary to the

NOESY experiment. First, the ROESY experiment enables one to distinguish NOE interactions from chemical exchange peaks that arise from a direct proton transfer between the water and the protein.^{7,11} For short mixing times, NOE peaks and chemical exchange peaks are always of opposite sign in ROESY. Second, NOEs may still be observable in ROESY, when the motional fluctuation of the internuclear interaction is in a time regime, where the cross-relaxation rate changes its sign in NOESY.¹¹ The 3D experiments are designed to help with the resonance assignment of complicated protein NMR spectra.

3 EXPERIMENTAL RESULTS

Figure 2 shows an example of a NOESY spectrum recorded for the observation of water–protein NOEs with an aqueous solution of basic pancreatic trypsin inhibitor (BPTI), a small protein containing 58 amino acid residues (see also **Pancreatic Trypsin Inhibitor**). The water–protein cross peaks are aligned along the ω_2 frequency axis at the ω_1 chemical shift of the water signal (arrow in Figure 2). From the corresponding ROESY experiment some of the cross peaks were identified as chemical exchange peaks of labile protein protons, like the amino protons of lysyl residues or the hydroxyl protons of tyrosyl residues. Furthermore, the 3D structure of BPTI and the set of NOEs observed with the hydroxyl protons of BPTI under different conditions suggest that a few additional cross peaks arise predominantly from the less interesting magnetization transfer pathway, where chemical exchange of water protons with labile hydroxyl protons of the protein is followed by intramolecular NOEs with nonlabile protein protons.¹² Yet, most of the cross peaks represent NOEs with protons that are close to four hydration water molecules trapped in the interior of the protein. All protein protons in the vicinity of these interior water molecules show NOEs with the water signal in the spectrum of Figure 2.

The NOEs between surface hydration water and BPTI are not visible in Figure 2, since these NOEs are very weak and they overlap with the exchange peaks and the NOEs with the interior hydration water molecules. NOEs with surface hydration water are more easily observed in NOESY and ROESY experiments with small peptides, which have fewer resonances and no interior water. Figure 3 shows the cross-sections taken at the ω_1 chemical shift of the water resonance in NOESY and ROESY experiments on the nonapeptide oxytocin. Almost the entire one-dimensional spectrum [Figure 3(a)] is represented by the water–peptide NOEs in these cross-sections, i.e. all protons are in contact with the solvent. The few positive cross peaks in the NOESY cross-section have chemical exchange contributions like the broad signal at 8.35 ppm, which comes from the amino protons of Cys-1. All negative cross peaks in the NOESY cross-section reflect direct intermolecular NOEs with hydration water. They are also present in the ROESY cross-section. The cross peaks between water and oxytocin are the only negative cross peaks of the NOESY spectrum, which was recorded at 6°C to ensure that all intramolecular NOESY cross peaks of oxytocin are positive. The water–oxytocin cross peaks become positive only at temperatures well below 0°C (with acetone added to prevent freezing).¹³ The negative sign of the NOESY cross peaks with the hydration water is clear

Figure 2 Spectral regions of a NOESY spectrum recorded at 4 °C with a 20 mM solution of BPTI in 90% H₂O/10% D₂O, pH 3.5. The arrow on the left indicates the frequency of the water signal with the intermolecular water–protein cross peaks along the ω_2 frequency axis. (Reproduced by permission of the American Chemical Society from Otting et al.⁵)

Figure 3 (a) One-dimensional NMR spectrum recorded at 6 °C with a 50 mM solution of oxytocin in 90% H₂O/10% D₂O, pH 3.5. (b) and (c) Cross-sections through, respectively, NOESY and ROESY spectra along ω_2 at the ω_1 frequency of the water line. Both spectra were recorded with 30 ms mixing time and the pulse sequence of Figure 1(b). The low-frequency half of the spectrum was inverted to revert the sign change in the excitation profile [Figure 1(b)]. (Reproduced by permission of the American Association for the Advancement of Science from Otting et al.²)

evidence for an increased modulation of the vectors connecting oxytocin protons with the protons of the hydration water. Model calculations show that the modulation must act on the subnanosecond timescale and is difficult to explain other than by the diffusion of the water molecules relative to the peptide.

4 THEORETICAL MODELS

In the limit of very short mixing times, the ratios of the cross-peak intensities over the diagonal peak intensities in, respectively, NOESY and ROESY, reflect directly the cross-relaxation rates σ^{NOE} and σ^{ROE} . Thereby, positive σ values lead to negative cross peaks and vice versa. The cross-relaxation rates σ^{NOE} and σ^{ROE} in NOESY and ROESY depend on the spectral density function $J(\omega)$.¹¹

$$\sigma^{\text{NOE}} = 6J(2\omega_0) - J(0) \quad (1)$$

$$\sigma^{\text{ROE}} = 3J(\omega_0) + 2J(0) \quad (2)$$

where ω_0 is the Larmor frequency of the protons. Equation (2) shows that σ^{ROE} is always positive because the spectral densities $J(\omega)$ are positive for all frequencies. In contrast, the sign of σ^{NOE} depends on the relative weight of $J(2\omega)$ and $J(0)$ [equation (1)]. The calculation of the spectral densities depends on the model used to describe the modulation of the dipole–dipole interaction.

Figure 4 shows three different models for which the spectral densities can be calculated from analytical formulas. In all three models the protein is approximated by a sphere undergoing free rotational diffusion, and the water–protein interaction is described as a two-spin interaction between a protein proton and a water proton. In model (a), a water molecule is rigidly bound to the protein surface,¹⁴ whereas in model (b) the water molecule is undergoing local motions in its hydration site, including rotations and a wobbling motion of an assumed hydrogen bond to the protein ('wobbling in a

Figure 4 Three models for the calculation of dipole–dipole cross-relaxation rates σ^{NOE} and σ^{ROE} between water protons and protein protons. (a) Isotropic rotational diffusion of a rigid sphere. The hydration water molecules are considered to be part of the sphere representing the protein. Squares represent polypeptide protons. The vector d_{12} connects a polypeptide proton with a hydration water proton, and d_{34} connects two polypeptide protons. τ_R is the correlation time for the overall rotation of the sphere. (b) Wobbling in a cone model. The residence time of the water molecules in the hydration sites is assumed to be long compared with the rotational correlation time τ_R of the sphere, which represents the hydrated protein, but the water rotates with a correlation time τ_F around a hydrogen bond to the protein, and this rotation axis is free to wobble with a correlation time τ_W within a cone with an opening angle $\theta_{\text{max}} = \pm 45^\circ$. (c) Random, independent translation and rotation of the protein and the water molecule. The two molecules are represented by spheres of radius r^P and r^W , respectively, with the proton spin displaced from the center by ρ^P and ρ^W . The translational diffusion coefficient D characterizes the relative translational motions of the two molecules. The two spheres reorientate isotropically with correlation times $\tau_{P/R}$ and $\tau_{W/R}$, respectively. (Reproduced by permission of the American Association for the Advancement of Science from Otting et al.²)

cone').^{15,16} In model (c), the water molecules are represented as spheres of smaller radius than the protein; both protein and water undergo free rotational and translational diffusion.¹⁷

The NOESY and ROESY cross relaxation rates calculated for the three different models of Figure 4 are compared in Figure 5. Model (a) describes the intramolecular cross relaxation between two polypeptide protons. At a Larmor frequency of 600 MHz, positive σ^{NOE} values are predicted for molecules with rotational correlation times τ_R shorter than about 300 ps. The rotational correlation times of oxytocin and BPTI at 5 °C were estimated from ^{13}C relaxation measurements to be 2 and 8 ns, respectively,² which is in line with the observation of negative σ^{NOE} values for the intraprotein NOEs in the NOESY spectra. The different sign of the σ^{NOE} values for water–protein NOEs cannot be explained by model (a), which assumes that the water–protein interaction can be described by the same parameters as the intramolecular NOEs in the protein.

The cross-relaxation rates in model (b) depend on the rotational correlation time of the protein and two further correlation times characterizing the wobbling in a cone motion

Figure 5 Cross-relaxation rates σ^{NOE} and σ^{ROE} for a pair of proton spins calculated for the three models of Figure 4. (a) Model of Figure 4(a) with a ^1H – ^1H distance of 2.0 Å; ^1H frequency 600 MHz. (b) wobbling in a cone model [Figure 4(b)]. H–O distance = 2.0 Å, $-\theta_{\text{max}} = 45^\circ$, $\tau_R = 2$ ns, ^1H frequency = 600 MHz. For $\tau_R = 8$ ns, the maximum value of $\sigma^{\text{NOE}}/\sigma^{\text{ROE}}$ over the complete range of the (τ_W, τ_R) -plane would be about -0.4. (c) Diffusion model [Figure 4(c)] with $r^W = 2.0$ Å, $\rho^W = 1.0$ Å, and $\tau_W/R = 4$ ps. The solid curve was calculated with $r^P = 12.0$ Å, $\rho^P = 11.0$ Å, ^1H frequency = 500 MHz, and $\tau_P/R = 8$ ns to simulate the intermolecular water proton–protein ^1H cross relaxation in BPTI at 4 °C. The broken curve was calculated with $r^P = 4.0$ Å, $\rho^P = 3.0$ Å, ^1H frequency = 600 MHz, and $\tau_R = 2$ ns to approximate the situation for oxytocin at 6 °C (Figure 3). At the bottom the inverse of the translational diffusion coefficient, $1/D$, was converted into the corresponding lifetimes of the hydration water molecules with the relation $\tau = x^2/D$ setting $\sqrt{x^2} = 4$ Å. (x^2 is the average square of displacement of a water molecule by diffusion.) (Reproduced by permission of the American Association for the Advancement of Science from Otting et al.²)

of the hydration water molecule. It turns out that for wobbling motions within a cone of $\pm 45^\circ$ opening angle, the ratio of $\sigma^{\text{NOE}}/\sigma^{\text{ROE}}$ is negative for all values of the correlation times τ_F and τ_W , which describe the frequency of the motions [Figure 5(b)]. This model would predict positive σ^{NOE} values only for significantly larger opening angles of the wobbling cone. However, this would displace the water molecule by more than its own diameter, so that a new water molecule is likely to fill the empty space left behind completing a chemical exchange reaction.

The diffusion model [Figure 4(c)] is the only model that describes the experimental data in a plausible way. The intermolecular cross-relaxation rates depend primarily on the diffusion coefficient. Positive σ^{NOE} values are predicted for diffusion coefficients larger than $3 \times 10^{-10} \text{ m}^2 \text{ s}^{-1}$, which is only about four times less than the self-diffusion coefficient of water at 5 °C. To obtain an impression of the short lifetime of protein hydration, it is instructive to convert the diffusion coefficient into a residence time of the hydration water near the protein using the Einstein–Smoluchowski relationship [caption of Figure 5(c)]. With the assumption that a water molecule has left its hydration site once it has diffused by more than 4 Å, the sign of the NOE changes for residence times shorter than about 0.5 ns. This time span is much shorter than the lifetime of a water molecule with respect to proton exchange,¹⁸ so that positive σ^{NOE} values must arise from the exchange of entire water molecules rather than proton dissociation.

Even the most sophisticated analytical model is a coarse approximation of the real situation. An improved calculation would have to take into account that the protein surface is not smooth, the amino acid side chains are flexible, and the water molecules are subject to orientating forces due to hydrogen bonding. In principle, the appropriate spectral densities could be calculated from a molecular dynamics simulation, except that the simulation would have to cover much longer times than what is computationally affordable today. A preliminary analysis has been based on a molecular dynamics calculation, where BPTI was simulated for over 1 ns in a water bath at 4 °C.¹⁹ In this simulation, the residence time of a bulk water molecule within the hydration shell of another bulk water molecule was found to be approximately four times shorter than the residence time of water near, e.g., backbone carbonyl groups, and no water molecule stayed for longer than 200 ps in the hydration shell of a given surface atom of BPTI.

5 COMPARISON WITH X-RAY DIFFRACTION STUDIES OF SINGLE CRYSTALS

Three-dimensional NOESY–TOCSY experiments recorded with BPTI showed, with a single exception, positive or vanishing cross-relaxation rates between the water protons and the protons on the protein surface, which indicates hydration lifetimes in the subnanosecond time range. Large positive cross-relaxation rates were exclusively observed with the four interior water molecules in BPTI.

The comparison of the intermolecular water–protein NOEs observed in BPTI with the hydration water molecules observed by X-ray crystallography provides an instructive example of a different view on protein hydration resulting from these two

methods.² The X-ray structures of three different crystal forms of BPTI have been determined at high resolution.^{20–22} All show the four interior water molecules completely shielded from access by the bulk water. The number and position of surface hydration water molecules varies between the different crystal structures, and only six out of about 60 X-ray-observable water molecules were found to have conserved hydrogen-bonding partners. There is no evidence from the NMR data that any of these conserved surface hydration water molecules are bound with lifetimes longer than 0.5 ns. The apparent discrepancies are explained by the fact that water is detected by X-ray diffraction, when the electron densities of the water molecules fall in the time average into the same place, irrespective of the actual residence times at the hydration sites. In contrast, the NOE is most sensitive to the residence times of the hydration water and thus is a good indicator of the intimacy of the protein–water contacts.

In special cases, longer residence times have been observed also for hydration water molecules that are accessible to bulk water. The best example is that of the well-ordered water molecules belonging to the ‘spin of hydration’ in the minor groove of DNA duplexes (see also *Nucleic Acids: Spectra, Structures, and Dynamics*). It is thought that the spine of hydration, which was first discovered by X-ray crystallography, is important for stabilizing the B-DNA conformation.²³ Strong, negative cross-relaxation rates were observed in the NOESY experiments between these hydration water molecules and the closest protons of the DNA, which shows that they must be bound for longer than 1 ns.^{24,25}

1 INTRODUCTION

I will begin with a few definitions. A **domain** is a compact structural unit in a protein; the amino-acid sequence need not be contiguous. **Modules** are a subset of domains that are contiguous in sequence and repeatedly used as 'building blocks' in functionally diverse proteins; they have identifiable amino-acid patterns that can be described by a 'consensus' sequence. A **repeat** is a modular unit that does not occur as a single copy – several repeats are needed to form a super-structure.

In the early 1970s, X-ray crystallography had been used to determine the 3D structures of relatively few proteins, yet it was already becoming apparent that they contained recurring domains.¹ In the 1980s, when sequence databases were beginning to expand, analysis of amino-acid sequences, revealed that many proteins were constructed in a modular fashion.^{2–8} By the 1990s, the idea of modular proteins was well established and hunting for new modules in the expanding sequence databases, by means of an identified consensus sequence, became a popular pastime. Efforts to classify modules and to evaluate their structure and function were also undertaken.^{9–12} Today, extensive databases of modules, identified by multiple sequence alignments and other data, have been created.¹³ These module databases are continuously being updated and annotated to incorporate new information gleaned from the expanding sequence and structural databases.

The number of protein modules is finite (~3000). They range in size from about 30 to 500 amino-acids. Since modules occur in most of the proteins in the various genomes, information about their structure and potential functions can have an impact on a wide range of fields. The diversity and spread of modular proteins is illustrated by a recent analysis of the entire *C. elegans* genome, in terms of extracellular modular proteins.¹⁴

Modules represent convenient and stable protein folds that have been found and retained during the evolution of biological systems. Once such a suitable structure, or scaffold, has been found, it can be used repeatedly in a variety of ways; some of which are shown schematically in Figure 1. One of the main uses of modules seems to

Figure 1 Some advantages of modular proteins. (a) Binding surfaces can be **presented**: (i) on different places on the same scaffold; (ii) on two or more modules to give extra variation; (iii) in different positions. (b) Various structures can be **assembled**: (i) with different covalent connections, including rigid end-to-end joins, flexible end-to-end joins or 'adapter' connections where the N- and C-termini are close together; (ii) complex non-covalent assemblies can be formed – examples include assembly at the T-cell surface, growth factor receptor complexes and the extracellular matrix. (c) Enzyme or receptor activity can be **regulated** by a module rearrangement

be to provide a binding surface to facilitate interactions between different macromolecules. The structural scaffold is the stable evolutionary entity; other features, such as the nature of the binding surface and the ways in which the modules are assembled, can evolve and change relatively rapidly to provide a range of functions. New modules can be inserted readily in a protein, because intron–exon boundaries, especially those in extracellular proteins, often correspond to module boundaries.⁷ Thus modules are sometimes inserted in a macromolecule as spacers, to present a binding function in the right position. Modular proteins also seem to be convenient for constructing larger assemblies. Examples include the formation of growth factor/receptor complexes that generate intracellular signals; another is the assembly of various receptors at the surface of T-cells, to form part of the immune response;^{15,16} further examples of modular assemblies include complexes involved in blood clotting and intracellular signalling. Flexible connections seem to be useful in assembling these modular arrays. Some connections between modules are thus found to be relatively rigid while, in other cases, the interface is highly flexible. Another role of intermodule flexibility is to allow a module rearrangement to provide regulatory 'on/off' control.

In this article I will briefly outline studies of module structure and function, largely from a personal viewpoint, but applications of nuclear magnetic resonance (NMR) to modular proteins will also be placed in a wider context. I will concentrate mainly on proteins found in the extracellular matrix, a heterogeneous assembly of proteins, proteoglycans and oligosaccharides that forms outside cells to perform a variety of essential functions.

2 MODULE STRUCTURE DETERMINATION

I first became involved in NMR studies of proteins in the early 1970s, when I collaborated with several Oxford colleagues to study a variety of enzymes.^{17–19} After an excursion into studies of cell suspensions,^{20,21} I returned to protein studies in the mid-1980s after it had been shown, mainly by Wüthrich, that solution-state structures of small

Figure 2 Representation of the structure of (a) epidermal growth factor (EGF), as determined by NMR. Cysteine (C) and glycine (G) residues that are conserved in EGF modules are indicated. Also shown are disulphide bonds (grey lines), β -sheets (large arrows) and helical regions (α). (b) is a schematic view of the structure of an EGF module that is found in a wide range of proteins; the observation of conserved amino-acids aspartate (D), tyrosine (Y) and a β -hydroxyaspartate (β), shown in bold lettering, predicts the presence of a calcium binding site

proteins could be solved ab initio. My first involvement with a protein module arose from collaboration with Brian Sheard, an ex co-worker in Rex Richards' lab. Brian was by then working at ICI Pharmaceuticals, and he persuaded me to try to solve the structure of epidermal growth factor (EGF). With Rob Cooke, Tony Wilkinson and others we published the structure in 1987.²² Our primary concern was to explain the role of EGF as an essential growth factor in terms of its structure. Although the general importance of protein modularity was not then widely realised, we did appreciate that the EGF fold occurred in other contexts. Almost as an aside in that paper, we drew attention to probable structural features of EGF homologues, including a calcium-binding site, that had been identified in several blood-clotting proteins (see Figure 2). EGF as a module is even more interesting than EGF as a growth factor, since it occurs in so many, essential extracellular proteins.²³ That initial paper led to a long line of experiments on EGF modules that are still going on in this lab – now mostly being done by Kristy Downing (see e.g., Refs.^{23,24})

After that first, somewhat serendipitous, foray into module research, we decided to attempt a more systematic approach. Our next venture depended heavily on a brave graduate student, Martin Baron. We thought we should try to express a module of unknown structure and we decided to try to study a type I module from human fibronectin. This was a high-risk project. We had no assay for correctness of fold and essentially no experience of protein expression. However, Martin exploited expertise on yeast expression available in the Kingsman lab in Oxford and managed not only to produce a folded module but also to determine its structure.²⁵ Using a similar approach, he later went on to solve the structure of the RGD-containing type 3 module from fibronectin (¹⁰F3) with Alison Main.²⁶ These early successes led to great interest and a supply of other protein modules from a number of collaborating labs. As a result we solved, in the next few years, several other module structures. These included the CP module,²⁷ found in a number of complement proteins, and the SH2²⁸ and SH3²⁹ modules found in intracellular kinases. Paul Driscoll also solved the structure of the first domain of the T-cell receptor, CD2; surprisingly the fact that this was an Ig module³⁰ was still controversial at that time. Some of the

extracellular modules structures solved in this lab are shown in Figure 3. They include ones that are predominantly helical and others that are exclusively β -sheet. The primary common feature they have is that they are used repeatedly by biological systems in different biological contexts.

The contributions of many other research groups to module structure determination must be acknowledged. Many of these structures have been solved using NMR but X-ray crystallography has been increasingly successful especially, recently, with larger modules (>200 amino-acids). Rather than catalogue these achievements here, the reader is referred to well-annotated, module databases.¹³ For example, in the SMART database, on 22nd April 2001, 530 modules are listed; about half of the 185 listed as 'extracellular' have known structure.

3 NMR AND PROTEIN MODULES

The study of modules and modular proteins embraces virtually the whole of modern molecular biology. What particular contributions can high-resolution solution-state NMR make? An obvious advantage of the method is that structures can be solved in solution, without recourse to crystals and heavy atom derivatives. However, as proteins get larger they seem to be easier to crystallise. The technology of X-ray crystallography has also improved dramatically over the last decade, with 3rd generation synchrotrons, cryo-cooling, CCD detectors and sophisticated data analysis packages becoming more readily available to a wide range of users. These advances, together with the fact that many of the more readily available, smaller protein structures have now been solved, have somewhat reduced the relative impact of NMR as a structural tool, since the early 1990s.

This does not mean that NMR plays an insignificant role. NMR technology has also improved in the last decade; 900 MHz spectra and cooled probes are now with us, yielding resolution and sensitivity beyond the dreams of a scientist beginning NMR in the 1970s. Devices such as isotope labelling, including deuteration, TROSY,³¹ increased tumbling rates,³² together with a range of multi-dimensional experiments can further enhance the available resolution. One

Figure 3 Some of the extracellular module structures determined in this laboratory in the last 12 years. More information can be obtained at <http://www.ocms.ox.ac.uk/idc/structures>. The symbols, nomenclature and colouring scheme of the modules is that used by the SMART database (<http://smart.embl-heidelberg.de/>; see also – <http://www.bork.embl-heidelberg.de/Modules/01-nomenclature.gif>)

problem with the NMR structure-determination methods that were developed in the 1980s, is that they depend on short-range distance information – mainly nuclear Overhauser effect (NOEs). New experiments to obtain longer-range information are now available, including use of long-range scalar coupling³³ and motional anisotropy that can be detected by analysis either of residual dipolar couplings (RDCs), introduced by partial alignment of the protein studied,³⁴ or of T_1/T_2 ratios of ^{15}N -labelled amide resonances.³⁵ Long-range information is particularly valuable when dealing with modular proteins.

A major advantage of NMR, compared to crystallography, is that it can deal with proteins that are very flexible, with no well-defined fold. It can also study weak ligand interactions and, perhaps most importantly, define relative motion in a system. Relative module motion can be very important for module assembly and regulation of function (Figure 1). While a crystal structure determination requires two modules to have a relatively fixed orientation, NMR can deal with various types of connection between modules. Some of the different ways that modules can be connected are shown schematically in Figure 4. The effect the different kinds of connection have on various NMR parameters is also summarised there. Intimate contact between modules leads to relatively large induced chemical shifts, many intermodule ^1H – ^1H NOEs and motional anisotropy that is greater than that observed for a single module. As the intermodule motion increases and contacts diminish, the detectable NMR effects are reduced.

In recent years we have concentrated more on how combinations of modules are assembled and how modules interact with their biological ligands than on structure determination per se. This forms part of an overall ‘dissect and rebuild’ strategy that we have applied for the last decade.⁹ This strategy will

Figure 4 Three different kinds of module connection that can exist in an assembly of modules. The different observed NMR parameters arising in the three situations are indicated on the right. If the modules have an intimate and rigid connection, then many ^1H – ^1H NOEs will be seen between modules. On addition of the second module, large induced chemical shifts and a significant increase in motional anisotropy will be introduced in the system. In the figure, $D_{\parallel}$ and $D_{\perp}$ represent axes of an axially symmetric diffusion tensor. Motional anisotropy can be measured by analysing T_1/T_2 ratios of ^{15}N amide resonances or by residual dipolar couplings (RDC) introduced by partial alignment of the system – e.g., by bicelles. In the completely uncoupled case, no NOEs or chemical shifts or will be induced upon covalent addition of a second module and there will be no increase in anisotropy. The ‘loose’ coupling case gives intermediate effects

now be illustrated, with reference to studies on a protein that we have studied for a number of years.³⁶ Features where NMR has particular advantages over other methods, such as studies of ligand binding, module assembly and module dynamics, will be emphasised.

4 A SPECIFIC EXAMPLE – FIBRONECTIN

Fibronectin is a large glycosylated protein found both in the extracellular matrix and in plasma.³⁷ It is a disulphide-linked dimer of two chains, each made up almost entirely of just three module types – type I (F1), type II (F2) and type III (F3). Fibronectin is involved in embryogenesis, wound healing and cell development. A measure of its importance is given by the fact that gene knockout is lethal at the embryo stage.³⁸ Some of the different functional regions of this molecule have been determined previously. For example the N-terminal F1 modules (¹F1–⁵F1) bind fibrin and bacteria; the ⁶F1.¹F2.²F2.⁷F1 region binds collagen, a major component of the extracellular matrix, and the ⁹F3.¹⁰F3 region binds to cell surface adhesion molecules called integrins; the ¹³F3.¹⁴F3 region binds heparin. The modular structure and binding functions of fibronectin are illustrated in Figure 5; note that the nomenclature ¹F1 means the first type I module.

One of many interesting features of fibronectin is that it is more active in binding to integrins when it is in the extracellular matrix, than when it is in plasma. Various hydrodynamic and other studies have suggested that this is because it is in a compact ‘pretzel’ form in plasma and an extended form in the matrix (see Ref.³⁹ and references therein). An ability to change shape like this requires considerable intermodule flexibility.

Consider first the N-terminal region, made up of the first five F1 modules. This region binds the clotting protein, fibrin, and several pathogenic bacteria, including *Staphylococcus aureus* and *Streptococcus pyogenes*. Studies of the ¹F1.²F1 pair showed no intermodule connections⁴⁰ while the ⁴F1.⁵F1 pair has been shown, using normal structure determination methods and relaxation anisotropy, to have a well-defined interface

and an extended structure.⁴¹ The bacterial binding proteins seem to start off as unfolded chains, but, in the complex, they zip up along the β -strands of the F1 modules.^{42,43} A good way of detecting these peptide/F1 interactions is to monitor chemical shifts induced in Heteronuclear Single Quantum Coherence (HSQC) spectra of ¹⁵N labelled protein. NMR is also good at detecting changes in motional anisotropy when the peptide binds. The ⁴F1.⁵F1 pair retains a similar, relatively large, anisotropy before and after a bacterial peptide binds across the two modules. In contrast, the ¹F1.²F1 pair starts off with an anisotropy expected for a single module and stiffens up to give a much higher anisotropy when a similar peptide binds across the two modules (Werner, J. et al., unpublished data).

The collagen-binding region of fibronectin has been shown to involve the region containing the ⁶F1.¹F2.²F2.⁷F1 stretch of modules. We have dissected this region extensively to explore its structure and function. The work includes studies of the ⁷F1, ¹F2 and ²F2 modules on their own, the ⁶F1.¹F2 pair⁴⁴ and the ⁶F1.¹F2.²F2 triple.⁴⁵ Interestingly the non-contiguous ⁶F1 and ²F2 modules come together to interact strongly in the triple. This interaction is readily detected, both by the observation of large shifts induced when the extra module is added, and by many NOEs detected across the interface. The ability of the triple to bind collagen also increases markedly compared to single and double modules.⁴⁵ Extensive studies of the ⁶F1.¹F2⁴⁶ and ¹F2.²F2⁴⁷ pairs have been carried out to define the relative motion of these modules in solution. The ⁶F1.¹F2 pair is relatively well defined and its structure can be refined using RDC and relaxation anisotropy data.⁴⁶ In contrast, the ¹F2.²F2 pair is completely ‘uncoupled’ and the addition of one module to the other induces no shifts and no increase in motional anisotropy.⁴⁷

Figure 5 The modular structure of fibronectin. This large extracellular matrix protein is a dimer of two chains, largely constructed from F1 (type I), F2 (type II) and F3 (type III) modules. Some functional regions are indicated – e.g., the N-terminal F1 modules bind fibrin. Some extra modules, such as EDA, EDB and IIICS are sometimes spliced into the molecule. Several single modules, as well as various combinations of modules, have been studied in this laboratory.³⁶ The F1 modules in the ⁴F1.⁵F1 pair are tightly associated⁴¹ and strong NOEs are seen across the module interface – for example between a tryptophan (cyan) and an arginine (blue). In a triplet of modules from the collagen-binding region,⁴⁵ the non-contiguous ⁶F1 and ²F2 modules make a tight interface with each other (residues in contact are shown in yellow and orange respectively). The two collagen-binding regions on the ²F2 modules, marked by a tryptophan (cyan), point away from each other. In the cell-binding region, ⁹F3.¹⁰F3 are known to be very important; ¹⁰F3 contains an RGD loop (cyan) that interacts with integrins. Additional binding affinity can arise from a site (yellow) on ⁹F3; NMR investigations of this module pair, derived from human^{49,50} and mouse⁵¹ fibronectin, have shown that the RGD loop is flexible and that the modules have a considerable degree of intermodule flexibility

The region of fibronectin that is mainly responsible for binding to cell surfaces via integrins is $^9\text{F3}$. $^{10}\text{F3}$. Particularly important is $^{10}\text{F3}$ that has a loop between β -strands containing the residues Arg.Gly.Asp (RGD). We determined the structure of $^{10}\text{F3}$ and showed that the RGD loop was flexible in solution.²⁶ For some integrins, such as $\alpha_5\beta_1$, an additional 'synergy' site on $^9\text{F3}$ is also needed before complete binding and biological activity of fibronectin is realised. There is a crystal structure of the $^7\text{F3}$ – $^{10}\text{F3}$ region that has clear electron density for the RGD loop, indicating that it is rigid in the crystal.⁴⁸ The relative orientation of $^9\text{F3}$ with respect to $^{10}\text{F3}$ is also well defined in the crystal, although they have a distinctly different relative orientation compared to other F3 pairs and the buried surface area between modules is relatively small. NMR studies of the $^9\text{F3}$. $^{10}\text{F3}$ pairs from human^{49,50} and mouse⁵¹ fibronectin showed that the RGD loop remains relatively flexible in solution and that the modules have a significant degree of intermodule flexibility. This is a good example of the complementary nature of NMR and X-ray crystal studies.

For structural studies of a large flexible molecule like fibronectin, a 'dissect and rebuild' strategy is going to be essential. While crystallography has been successful in defining the structure of stretches of F3 domains,^{48,52} NMR has also made significant contributions. In the case of the $^9\text{F3}$. $^{10}\text{F3}$ cell-binding region, NMR complemented X-ray studies by showing that the F3 modules can have significantly more flexibility than shown in the crystals. Only NMR structures are available for fibronectin F1 and F2 modules; NMR studies of several pairs ($^1\text{F1}$. $^2\text{F1}$, $^4\text{F1}$. $^5\text{F1}$, $^6\text{F1}$. $^1\text{F2}$ and $^1\text{F2}$. $^2\text{F2}$) have revealed several different kinds of connection with different flexibility. NMR is also a very powerful tool in defining how fibronectin interacts with its various biological ligands by following induced chemical shifts and by analysing motional anisotropy. It is worth noting that NMR can also be applied to many other large modular proteins like fibronectin; an example is fibrillin, that is associated with the genetic disease the Marfan syndrome.²⁴

5 THE FUTURE

Protein module research has made great strides in the last decade. In the new millennium, modules appear to be ideal targets for a co-ordinated program in 'Structural Genomics' that aims to determine representative structures of the protein folds found in biological systems. It seems likely that the structure of at least one representative module from all module classes found in biology will have been solved within the next decade. This knowledge will allow features of proteins in all genomes to be modelled reasonably accurately. What will remain unknown, in many cases, is how the modules are used by biology to perform their function in a complex and dynamic macromolecular assembly. In other words much will remain to be done in 'Functional Genomics', that aims to define the biological role of all the genomic products. This will require investigations of how modules are joined together in a modular protein, the extent of intermodule flexibility and the nature of their various interactions. It seems likely that NMR will continue to make a very significant contribution to this area of research in the foreseeable future.

Significant technical advances are also likely to continue in NMR, as they have done over the last 55 years. As mentioned

above, higher fields, long-range structural restraints and other techniques promise to facilitate NMR structure determination. Advances are also likely in other areas. Chemical shifts are the most precise probes of subtle structural changes, yet they are hard to interpret in a quantitative way. Ab initio density functional theory calculations of chemical shielding of small molecular systems are now feasible because of the availability of the Gaussian suite of computational chemistry programs. This is likely to enhance our understanding and hence the power of NMR methods in the future. The most difficult part of a programme to investigate modules, however, is the production of large amounts of pure, folded, well-behaved, isotopically labelled protein. Current worldwide efforts to produce proteins on a large scale for structural studies will have a large impact in this area. An ability to splice in a labelled module⁵³ among a series of unlabelled ones will also greatly enhance and extend the size of module assemblies that can be studied.

1 INTRODUCTION

There is currently a great deal of interest in the mechanism of protein folding, and a number of theoretical and experimental approaches to the problem have been developed in the past few years. Advances in hardware and software have made NMR an exceptionally important technique for studies of protein folding; it has been used to obtain novel insights into the folding process. The development of quench-flow hydrogen exchange methods¹ has opened up a new window into folding events that occur on the millisecond to second timescale. Using known resonance assignments for the folded form of the protein, it has been possible to obtain assignments and structural information on unfolded forms² and folding intermediates.³ Insights into the earliest steps of the folding process have been provided by NMR studies of peptide fragments of proteins.⁴ These and other studies on the protein folding process will be briefly reviewed in this article; limitations of space prevent an exhaustive review.

2 FOLDING PATHWAYS OF PROTEINS BY NMR

2.1 Slow Folding Events and Equilibrium Studies

Since the timescale of the NMR experiment is slow compared with classic optical spectroscopic methods for measuring kinetics, the use of NMR to monitor protein folding processes directly is not usually possible. Folding can be observed by NMR, and rate information can be extracted from the measurements. For example, an upper limit of the rate of the slow unfolding of trp repressor in urea was estimated to be 50 s^{-1} from the observation of separate signals in 4 M urea corresponding to the native and unfolded states.⁵ Attempts have been made to detect intermediates by NMR spectroscopy at equilibrium in the folding–unfolding reaction,^{1,6} and NMR has been used to demonstrate independent unfolding of the domains of urokinase.⁷ In general these methods give information only on the slowest steps of protein folding.

A variety of NMR techniques has been used to study one of the well-known slow processes in protein folding, the *cis*–*trans* isomerization of prolines. A number of studies have utilized magnetization transfer NMR, which, under favorable conditions, can also be used to obtain information on the kinetics of protein folding itself.⁸ The magnetization transfer technique has been used for staphylococcal nuclease to demonstrate the presence of two native states that differ in the isomerization state of Pro-117^{9,10} and to study the folding and interconversion of these two forms.¹⁰ A peptide model of the site of isomerization did not show any evidence of *cis* isomeric forms in aqueous solution, an indication that they are probably absent in the fully unfolded form of staphylococcal nuclease.¹¹ Differences in rates of isomerization of prolines in the presence of isomerases have been studied by dynamic NMR spectroscopy.¹²

2.2 NMR Hydrogen Exchange Pulse Labeling

An important advance in the understanding of the structural basis of protein folding came with the realization that a combination of quenched-flow methods, hydrogen–deuterium exchange and NMR could give detailed site-specific information about the folding process (see Roder¹ and Englander and Mayne¹³ for reviews). The method was suggested by Roder and Wüthrich¹⁴ as an extension of the ^1H – ^3H exchange methods developed by Baldwin and co-workers,^{15,16} and its power was demonstrated in 1988 with the simultaneous publication of two folding studies, one on ribonuclease A¹⁷ and one on cytochrome *c*.¹⁸ Since then, a number of proteins have been studied by the hydrogen exchange pulse-labeling method, and representative examples will be discussed below.

The method aims to label intermediates in the folding pathway in such a way that they can be studied at leisure by NMR once folding is complete. There are many advantages of working with native folded proteins, including greater stability to aggregation at NMR concentrations, better dispersion of resonances in the NMR spectra, and usually more readily available resonance assignments. The pulse labeling technique requires the use of a sophisticated temperature-controlled syringe system, obtainable from several commercial sources. For folding studies, a 5-syringe unit is used, as shown in Figure 1. Mixing is performed in mixing chambers fed by computer-controlled drive syringes. For a typical refolding experiment, the protein can be pulse-labeled either with $^1\text{H}_2\text{O}$ from a $^2\text{H}_2\text{O}$ buffer^{17–19} or with $^2\text{H}_2\text{O}$ from a $^1\text{H}_2\text{O}$ buffer.²⁰ Denatured protein (S1) is rapidly diluted with refolding buffer (S2) and allowed to refold for variable times determined by the length of the delay line DL-1. The lower limit of the refolding time is determined by the mixing characteristics of the quenched-flow apparatus and is usually 4–6 ms or more. The partially refolded protein is pulse-labeled (S3, M2) for about 50 ms (DL-2) under conditions where the intrinsic peptide hydrogen exchange time constant is about 1 ms.²¹ The amide protons in unstructured parts of the protein are exchanged during the pulse, but the protons that are involved in hydrogen-bonded secondary structure (and which are slowly exchanging in the native protein; see below) are protected from exchange. The labeling pulse is quenched (S4, M3) by lowering the pH to conditions where amide proton exchange is slow, and the folding process allowed to proceed to completion

Figure 1 Schematic diagram showing the arrangement of syringes, mixing chambers, and delay lines in the Bio-Logic QFM-5 quench-flow apparatus, one of several commercially available systems. Jennings from the manual for the Bio-Logic quench-flow apparatus with permission)

in the sample collection syringe. A schematic picture of the stages in the quench-flow pulse-labeling experiment with the denatured protein in $^1\text{H}_2\text{O}$ and the labeling pulse in $^2\text{H}_2\text{O}$ is shown in Figure 2.

Quench-flow hydrogen exchange studies of the folding of a number of proteins have now been reported. It is interesting to note that there has so far been little similarity revealed in these studies between the folding mechanisms of proteins in different structural families. For ribonuclease A (disulfide bonds intact),^{17,19} one early folding intermediate is formed rapidly and contains all of the slowly exchanging amide protons in the β -sheet. These protons are only marginally protected early in the folding pathway, but become more protected at later stages, an indication that subsequent events stabilize the formation of the sheet. There are only a few

Figure 2 Schematic diagram showing the state of the protein at various stages in the mixing and labeling process

probes (i.e. only a few slowly exchanging amide protons in the native folded state) in the three helices, so information is scanty in these regions. An analysis of the results in terms of a sequential model for folding showed that the intermediate contains the majority of the β -sheet secondary structure of ribonuclease A, but is not fully populated when first formed.¹⁹

The structure of cytochrome *c* is quite different from that of ribonuclease A, and consists largely of helix, with little or no β -sheet. Unlike ribonuclease A, there are a large number of amide proton probes in the helices, so this molecule provides a good system for study of the folding of a helical protein.¹⁸ Several amide protons in the N- and C-terminal helices are apparently protected within the 4 ms dead time of the quench-flow apparatus, an indication that folding is initiated very rapidly in these regions of the protein, probably by rapid formation of helical secondary structure, followed by or perhaps concomitant with stabilization of the initial folded form by docking of the two helices. This behavior is apparently different from that of the α/β protein ribonuclease A, although it is difficult to determine whether the helices are in fact formed early in the latter protein, due to the lack of probes in the helices. A two-peptide model of the cytochrome *c* folding intermediate showed enhanced helicity by NMR when the two component peptides were combined,²² indicating that interactions between marginally stable elements of secondary structure are important in forming tertiary subdomains (intermediates) in the folding of the intact protein.

The folding pathways of ribonuclease A and cytochrome *c* appear to be rather simple, consistent with the small size of the proteins and their compact single-domain structure. Lysozyme shows more complex folding behavior, giving evidence of multiple pathways associated with two folding domains.^{23,24} NMR experiments based on competition between hydrogen exchange and the refolding process²³ showed that the rapid and slow refolding populations of lysozyme correspond to the helical and sheet regions of the molecule respectively, an indication that the two domains fold independently. In addition, different populations of molecules fold by kinetically distinct, parallel pathways, some of which may involve reorganization of incorrectly folded structure.²⁴

Parallel folding pathways have also been invoked to explain the results obtained for the folding of ribonuclease T₁,²⁵ which folds much more slowly than most other proteins studied by the quench-flow hydrogen exchange method. Two intermediates were postulated on the kinetic folding pathway of ribonuclease T₁, a native-like intermediate and a molten globule.²⁵ Molten globule intermediates have been suggested for many of the protein folding pathways studied so far, although the definition of what constitutes a molten globule sometimes appears to vary with the protein studied. Intermediates of this kind were postulated for T4 lysozyme,²⁶ ubiquitin,²⁷ and barnase,²⁸ with the interesting similarity in these cases that both α -helices and β -sheets containing stable backbone hydrogen bonds were formed in the earliest folding events (within a few milliseconds). In contrast, refolding of the all- β -sheet protein interleukin-1 β leads to rapid formation (within 25 ms) of an intermediate containing 90% of the β -sheet secondary structure but without stable hydrogen bonds.²⁹ Formation of stable, hydrogen-bonded secondary structure begins only after ~ 1 s. Another all- β -sheet protein, plastocyanin, displays

similar behavior: a folding intermediate containing unstable β -sheet structure is formed, which provides only slight protection of backbone amide protons from exchange.³⁰ Isomerization of a key proline residue, Pro-16, to the *cis* form allows correct packing of the incipient, fluxional β -sheets to form stable, hydrogen-bonded secondary structure during the final, slow, folding step.

While the evidence that molten globule intermediates of many types participate in the folding pathways of a number of proteins is persuasive, in none of the systems described so far was the intermediate demonstrated to participate in the actual kinetic folding pathway of the protein. In one well-studied system, that of apomyoglobin, the intermediate observed in equilibrium experiments has been shown to be identical to that observed by the quench-flow NMR hydrogen exchange method. Further, the intermediate was shown to be on the kinetic pathway of folding, the first demonstration of such a phenomenon.

Myoglobin and apomyoglobin (without the heme prosthetic group) have been studied extensively both by theoretical and experimental techniques. Circular dichroism (CD) spectroscopic measurements as a function of pH³¹ indicated that a stable intermediate species exists at pH $\sim$ 4. The structure of this species has been characterized by amide exchange trapping³² (see later), which showed that a region of the protein is folded in the intermediate, while the rest of the protein is flexible or unfolded. The folded region consists of the two C-terminal helices, termed the G- and H-helices, which form a helical hairpin structure in the fully folded myoglobin and also probably in apomyoglobin,^{33,34} together with the N-terminal helix, termed the A-helix. These regions are shown mapped onto the structure of native myoglobin in Figure 3. The question as to whether this intermediate is formed during the folding of apomyoglobin was addressed by Jennings and Wright.²⁰ Using both hydrogen exchange pulse labeling and stopped-flow CD measurements they showed that an intermediate was formed in less than 5 ms, where amide proton probes were fully protected in the A-, G-, and H-helical regions of the protein and a part of the B-helix. Slower folding steps saw the protection of the remainder of the B-helix, the C- and E-helices and the CD connecting loop. These regions are precisely the same as those previously identified as being folded in the equilibrium intermediate observed at pH $\sim$ 4. There is clearly a close structural similarity between the earliest detectable kinetic intermediate and the intermediate observed under equilibrium conditions,³² providing strong evidence that this molten globule intermediate participates in the kinetic folding pathway.

2.3 NMR Amide Exchange Trapping

The NMR quench-flow pulse-labeling method has a problem, particularly severe for smaller proteins: only a subset of the NH protons can be studied. Only those amide protons that are resistant to exchange into $^2\text{H}_2\text{O}$ in the native protein during the experiment can be used as probes during the kinetic folding studies. In addition, most of the probe amide protons are usually present in regular secondary structure: if these are all protected in a folding intermediate, then there is little information to be gained on the sequence of folding events, and it is unclear whether the amide protons are protected in native-like secondary structure in the intermediate. A partial

Figure 3 Location of the structured regions found in the kinetic intermediate of apomyoglobin, mapped onto the X-ray structure¹⁰⁶ of the native protein (the heme group is omitted from the diagram for the sake of clarity). Helices B–E are unshaded and are proposed to be predominantly unfolded in the intermediate. The F-helix is unshaded to denote the absence of amide proton probes and structural information. The A-, G-, and H-helices are darkly shaded, and are proposed to be folded into a native-like structure in the intermediate. (Reproduced by permission from Hughson et al.³²)

solution to this problem is available in the form of the amide exchange trapping experiment.^{35,36} In this experiment, both the locations and the hydrogen exchange rates (protection factors) of the protected amide protons are measured. A comparison of the protection factors for the intermediate and for the native state of the protein can then be used to determine whether the hydrogen-bonded secondary structure in the intermediate is native-like. As mentioned above, this method was used to show that the low pH intermediate of apomyoglobin contained native-like secondary structure.³² An extensive study of cytochrome *c* using this technique was made by Englander and co-workers,^{37,38} who concluded that native-like secondary structure was formed in the cytochrome *c* folding intermediates (termed submolecular folding units) that are formed at low pH in high salt.

The partially folded state of α -lactalbumin (termed the A-state or molten globule state) is also formed at low pH and has been characterized by NMR pH-jump refolding studies³⁹ and by amide exchange trapping.⁴⁰ A specific element of residual secondary structure present in the A-state of α -lactalbumin³⁹ is thought to be native-like, and to consist of two helices, with a region of highly compact (though not necessarily native-like) hydrophobic packing between them. The highly protected nature of this hydrophobic region is shown by the high degree of protection of an indole NH from a Trp residue in the A-state. The method has been applied to proteins denatured by alcohols, monellin in ethanol or trifluoroethanol,⁴¹ and lysozyme in trifluoroethanol.⁴² The characteristic feature of these alcohol-denatured states appears to be a higher content of helical secondary structure than the native state. The amide exchange trapping experiment demonstrated that, in the case

of monellin, a specific part of the molecule had apparently changed from β -sheet secondary structure in the native protein to α -helix.⁴¹ By contrast, the protected amides found in the experiments on alcohol-denatured lysozyme were present in regions that were helical in the native folded state, and little protection was found for the sheet and loop regions of the protein. For lysozyme, the side chains were found to be averaged.⁴²

3 NMR OF DENATURED PROTEINS

The study of the denatured states of proteins is difficult, for several reasons. The denatured state of a protein is prone to aggregation, especially at NMR concentrations, the solution conditions under which denatured proteins are studied are often not ideal for NMR, and the spectra themselves are often highly overlapped, consistent with the generally random nature of the polypeptide chain. However, contrary to earlier assumptions, the denatured state may not be 'simply' a random coil, but may contain residual structure, as has been found for some peptides (see later). Direct measurement of amide proton exchange rates in heat-denatured ribonuclease A showed no difference from that expected for a disordered peptide, though some anomalies in the pH dependence were pointed out.⁴³ This was despite the observation of residual signal in the CD spectrum, which could be eliminated by the addition of denaturing agents. The authors concluded that no stable hydrogen-bonded secondary structure was present in thermally denatured ribonuclease A.

The ribonuclease experiments were performed as a high-temperature variant of the original quench-flow experiment,¹⁷ which, as explained above, makes the actual NMR measurements on the native state after reconstitution. Direct measurements of the resonances of the denatured state and their assignment by exchange correlation have also been made for ribonuclease A.⁴⁴ Exchange correlation has also been used for lysozyme to demonstrate the presence of hydrophobic clusters in the thermally denatured protein.⁴⁵ An interesting new application of the photochemically induced dynamic nuclear polarization (CIDNP) technique has also been used for lysozyme to confirm the presence of hydrophobic interactions involving some of the Trp residues buried in the native state of the protein.⁴⁶ In these experiments, the lysozyme denatured by dimethyl sulfoxide appeared to have more random behavior than that denatured by urea or high temperatures, a further indication that hydrophobic interactions are involved.

While NMR is potentially a powerful method for direct characterization of residual structure and dynamics of unfolded proteins, applications have been rather limited to date because of the difficulty of assigning the poorly dispersed spectrum of the unfolded state. In one approach, resonance assignments in a urea-unfolded fragment of 434 repressor were made using chemical exchange to transfer assignments from the folded to the unfolded species.^{47,48} From NOE measurements on the 434 repressor fragments in 7 M urea, specific hydrophobic interactions were identified and the local structure of the polypeptide chain in this vicinity was calculated.⁴⁹ The residual structure in the urea-denatured protein is similar to the corresponding region in the structure of the native protein, prompting the hypothesis that the formation of this hydrophobic cluster could serve as an initiation site for the folding of the repressor.

More recently, heteronuclear multidimensional NMR methods have been applied to obtain ^1H , ^{13}C , and ^{15}N resonance assignments for uniformly labeled FK506 binding protein unfolded in 6.3 M urea or 2 M guanidine hydrochloride.⁵⁰ Although the protein displayed extensive conformational averaging, local regions of secondary structure could be identified. These methods should be generally applicable for NMR structural studies of unfolded or partly folded proteins, and have now been applied to a denatured 131-residue fragment of staphylococcal nuclease.⁵¹

4 NMR OF PROTEIN FOLDING INTERMEDIATES AND PARTIALLY FOLDED STRUCTURES

For most proteins, the intermediates formed during the folding process are populated only transiently, so that under normal circumstances they cannot be directly studied by NMR. Experiments such as quench-flow hydrogen exchange and amide proton trapping are generally the preferred methods to give information on these states. In some proteins, under certain conditions, folding intermediates can be directly observed. Ingenious experimental design, such as the continuous recycled-flow method,⁵² have been used to circumvent the problems of the short lifetimes of intermediates.

Partly folded forms of several proteins have been studied by NMR. Of these, the most extensive studies have been on ubiquitin, α -lactalbumin, and bovine pancreatic trypsin inhibitor (BPTI). The A-state of ubiquitin is present at pH ~ 2 in 60% methanol/40% water at 298 K, and three separate studies of the same state of the protein^{53–55} reach broadly similar conclusions that nevertheless differ considerably in detail (an illustration of the difficulties inherent in these types of measurements). Harding et al.⁵³ used two-dimensional (2D) ^1H NMR spectroscopy to assign slowly exchanging amide proton resonances in the A-state, concluding that there was no gross structural reorganization from the native state of the protein but that the A-state contained a subset of the secondary structure found in the native state, including the first two strands of the 5-strand β -sheet, part of the third strand, and a partially structured α -helix packed on the hydrophobic side of the sheet. No evidence was found for the turns and 3_{10} helical structure present in the native state of the protein.

Pan and Briggs⁵⁴ made an extensive study of the protection factors of amide protons in the A-state of ubiquitin. They too found a structure with native-like secondary structure, but concluded that almost all of the native secondary structure persists in the intermediate, apparently destabilized by several kilojoules per mole compared with the native form of the protein. Differences in the method of sample preparation were thought to account for the differences in the results between the two studies. In a third study, this time using heteronuclear three-dimensional methods, Stockman et al.⁵⁵ were able to assign unambiguously more than 90% of the resonances of the A-state in 60% methanol, and to resolve a number of NOEs that define the limits of secondary structure. These results indicate that, contrary to the conclusions of the two previous studies, only the first two β -strands are present in the A-state, and suggest that the C-terminus, rather than being part of the β -sheet as in the native protein, becomes helical in the presence of methanol, an interesting parallel to the behavior of monellin.⁴¹

The ^1H NMR spectrum of the A-state of α -lactalbumin formed at acid pH differs substantially from those of both the native and denatured states.³⁹ Chemical shift dispersion in the A-state is limited, indicating that long-range tertiary structure present in the native state is absent in the intermediate.⁵⁶ No evidence for native-like hydrophobic clustering is observed, but interresidue NOEs indicate that a new aromatic cluster, consisting of residues at positions 103, 104, and 107 in the polypeptide chain, is present. The identity of this structure as a local interaction is confirmed by the observation of similar NOEs in a short peptide containing these residues.⁵⁶ These residues form part of a helix in the native form of the protein, and the stabilization of helices by $(i, i + 1, i + 4)$ hydrophobic interactions has previously been noted.^{57,58} It is possible that this sequence behaves in the A-state of α -lactalbumin like the nascent helix observed in peptide fragments of proteins⁵⁸ (see later), as a precursor to the formation of helical structures in the folded protein.

The most intensely studied protein, in terms of folding, is probably BPTI. Recently, a number of studies using NMR to probe the structure of the folding intermediates containing only one or two of the three disulfides of the native protein have been performed, using mutant proteins where various Cys residues have been replaced by Ser^{59–61} or Ala.⁶² The intermediates generally show many of the characteristics of the folded form of BPTI, although a Cys-Ser mutant containing only the 30–51 disulfide appears from NMR studies to be largely unfolded at the N-terminus.⁶⁰ However, the secondary structure that forms the core of the molecule is already formed and stabilized by hydrogen bonds even in the presence of only one disulfide bond.^{59,61} A disulfide-bridged peptide mimic of the helix/sheet secondary structure of BPTI was also shown to be folded.⁶³ It thus appears that much of the folding process of BPTI is achieved before the first disulfide is even formed, and the intermediates modeled by the mutant proteins are sufficiently stable to be studied at length by NMR.

Another long-lived folding intermediate that has been studied by NMR is the partially folded form of subtilisin BPN', which cannot form the native, fully folded protein in the absence of a 77-amino acid pro-sequence.⁶⁴ The intermediate possesses secondary structure, but tertiary structure only in small regions, including the location of a high-affinity calcium-binding site. The authors conclude that the function of the pro-sequence is to lower the energy of the transition state between the intermediate and the fully folded molecule.

5 NMR OF PEPTIDE FRAGMENTS OF PROTEINS

The power of NMR methods in the study of protein folding is emphasized by the quantity and variety of research reported to date, and the continuing development of new techniques, as briefly described above. NMR is able to describe folding intermediates and processes in a site-specific manner that cannot be rivaled by any other technique, but is limited at present to a timescale of milliseconds or longer. For most proteins, a number of steps in the folding process are already complete in 5 ms; for apomyoglobin, for example, the first intermediate is already fully formed in this time.²⁰ The earliest events in the folding process (Figure 4) are thus not amenable to direct study by NMR spectroscopy on the whole protein. An approach to characterize the probable initiation events in

Figure 4 Schematic diagram of the folding process

protein folding has been proposed^{65,66} in which the protein is dissected into peptide fragments, and NMR methods are used to identify elements of secondary structure or hydrophobic clustering in aqueous solution. The majority of linear peptides are unstructured in aqueous solution, that is, they are present as a conformational ensemble containing conformers with widely different structures. For some peptides it is possible to observe a conformational preference for a folded form. However, it should be stressed firmly that, in the absence of covalent conformational constraints, all linear peptides must be considered to consist of conformational ensembles in solution. Even cyclic peptides are flexible, and their NMR spectra show signs of conformational averaging.

The S-peptide of ribonuclease A was the first peptide for which a conformational preference for a folded helical form was observed, by CD spectroscopy, in aqueous solution.⁶⁷ One-dimensional NMR was later used to demonstrate the formation and dissolution of secondary structure in the S-peptide⁶⁸ and in three-residue peptides from other regions of ribonuclease A.⁶⁹ Turn-like conformations were inferred from the latter data, consistent with the hypothesis that the formation of β -turns is important in the initiation of folding of ribonuclease A. A conformational preference for a well-defined turn was found using 2D NMR methods in a nine-residue peptide derived from influenza virus hemagglutinin.⁷⁰ Since then, many studies of peptide fragments of protein have been reported, a selection of which will be summarized below. Several reviews have recently appeared on this subject, including a summary of the techniques used for identifying structured states in the conformational ensemble.⁷¹ The connection between the NMR observation of structured conformers in peptide fragments of proteins and the initiation of protein folding was initially suggested in 1988:⁶⁵ since that time evidence has accumulated that peptides can be used as models for the initiation of protein folding, and some surprising behavior relevant to the folding process has also been seen.

5.1 Turn Conformations Observed in Peptides by NMR

Turn conformations are logical sites for initiation of protein folding. While much is known of the sequence

preferences of turn conformations in folded proteins from a consideration of X-ray structures,⁷² the incidence of turns in unfolded proteins and by implication in peptides was unknown. Following the original discovery of the turn conformation in the hemagglutinin peptide,⁷⁰ an extensive study of the sequence preferences of turns was made in several series of five-residue peptides.⁷³ The original turn conformation was present in the sequence Tyr-Pro-Tyr-Asp-Val with a *trans* configuration of the Tyr-Pro peptide bond; by varying the amino acid residues at each position of the turn, while keeping the other residues constant, a profile of the ideal turn-forming sequence in a peptide or unfolded protein was obtained. The best residue for turn formation at position 3 is glycine (Gly), and at position 4 is Asp.⁷³ If these two residues are kept constant and position 1 of the turn is varied, the residue that most favors turn formation is Ala.⁷⁴ The best residue at position 2 is the original Pro, but, perhaps surprisingly, peptides in the series Ala-X-Gly-Asp-Val, with X other than Pro, also contain substantial turn populations,⁷⁴ an indication that the Pro residue is not essential at position 2 as long as the other three residues are favorable for turn formation.

We thus conclude that, for peptides in solution, the optimal sequence for turn formation is Ala-Pro-Gly-Asp. While many of the examples of this and similar sequences do form turns in protein structures, this is not always the case. This is an illustration of the difference between the relatively fixed conformation in the folded protein, where many factors including long-range tertiary interactions can influence the local backbone conformation, and the flexible conformation in the linear peptide, where unfolded states are always accessible and the observation is of a conformational preference only. A corollary of this is that the conformational preferences observed in peptides or unfolded proteins need not necessarily be present as a structure in the final folded protein, even if the preference observed in the peptide is indeed a site of initiation of protein folding. The initial events probably involve the restriction of conformational space by the reversible formation of structures such as turns. Since this process is rapid and reversible, the initial turn conformation could be eliminated from the final structure by subsequent folding events that make other conformations more energetically favorable for this particular sequence. Nevertheless, a correlation has been observed between the values obtained for the turn propensity in peptides and the empirical sequence preferences obtained from protein structures,⁷³ an important link between the behavior of peptides in solution and structure in proteins (Figure 5).

The population of the turn conformation in Tyr-Pro-Gly-Asp-Val containing the *trans* form of the Tyr-Pro peptide bond was estimated to be approximately 50%, and it showed behavior more consistent with turn type II than type I.⁷³ By contrast, the *cis* form of several peptides with sequences such as Ser-Tyr-Pro-Tyr-Asp-Val showed evidence of an exceptionally high population of a different turn conformation, identified as type VI, in the four-residue sequence Ser-Tyr-Pro-Tyr.⁷³ A sequence dependence of this turn conformation showed that it was highly favored when there were aromatic residues on either side of the *cis* Pro, and when Asp was present at position 5, following the turn.⁷⁵ Since the population of the folded conformation was so high (>70% of the *cis* peptide), and since its structure did not obviously correspond to any well-known secondary structure, a three-dimensional

Figure 5 Probability of the occurrence of a turn conformation in a particular sequence in a folded protein⁷² plotted against the temperature coefficient observed for the amide proton at position 4 in the series of peptides Tyr-Pro-X-Asp-Val, where X is any amino acid residue. The letters are the single-letter codes for the amino acids at position 3. (Adapted with permission from Dyson et al.⁷³)

structure of the folded form of one of the peptides, Ser-Tyr-Pro-Phe-Asp-Val, was calculated.⁷⁶ It was essential to exclude NOE contributions from the unstructured states of the peptide from the constraint list for structure calculation. The structure reveals a specific stacking interaction between the two aromatic rings and the Pro ring, which explains not only the stability of this conformation in solution, but also several unusual features of the NMR spectrum, including the low-frequency shifted resonances of the *cis* Pro. The stability and high population of the structure is attested to by the results of an NOE/ROE study of the hydration of Ser-Tyr-Pro-Phe-Asp-Val,⁷⁷ which shows that the Pro ring protons with the furthest low-frequency shifted resonances are differentially protected from solvent, consistent with their presence in a highly populated structure where they are closely stacked onto the adjacent aromatic rings.

Specific turn conformations in proteins and other polypeptides have been modeled by studying peptides in solution. In particular, it was found using NOE experiments that the internalization sequence of the low-density lipoprotein receptor adopts a turn conformation in solution,⁷⁸ an important piece of information both for understanding of surface recognition and export and for molecular design. A result relevant to the problem of protein folding in vivo was the discovery that the sequence that is altered in temperature-sensitive mutants of the P22 phage tailspike protein, which had been shown to be deficient in the folding of the protein at the restrictive temperature,⁷⁹ contains a conformational preference for a turn in a peptide corresponding to the wild-type sequence, but not in the corresponding peptide with the mutant sequence.⁸⁰ These results provide convincing support for the importance of turn formation in the initiation of folding of proteins.

5.2 Helices and Nascent Helices

A conformational preference for helix in a peptide is easier to detect by CD spectroscopy than is a preference for a turn conformation, though this is possible if the peptide is sufficiently short.⁷³ Helices are indicated by NMR through

observation of medium range NOEs and small $^3J(\text{H,N-}\alpha)$ coupling constants,⁸¹ and peptides that contain helices according to the CD spectrum have also been shown to do so by NMR.^{82,83} The site-specific information obtained from the NMR experiment allows the determination of the location and, to a certain extent, the local population of the helix: in most cases it appears that the helix is most populated in the center of the peptide, and frayed toward the ends. Even in the most highly helical peptides, however, unfolded forms are present in solution.^{82,83}

NMR is a more sensitive technique for the detection of helix-like forms than CD; for detection of helix by CD, it must be quite regular.⁸⁴ An interesting structure detected by NMR in linear peptides is the so-called nascent helix,⁵⁸ which is characterized by $d_{\text{NN}}(i, i + 1)$ NOEs, intermediate-to-small $^3J(\text{H,N-}\alpha)$ values, intermediate-to-low amide-proton temperature coefficients, and the presence of a number of $d_{\alpha\text{N}}(i, i + 2)$ NOEs, which are normally associated with turns.⁷¹ The nascent helical peptide can readily be induced to form ordered helix by the addition of solvents such as trifluoroethanol (TFE). These results are interpreted in terms of a molecular model in which folding (and unfolding) of helices proceeds by way of turn-like intermediates. Indeed, such structures are populated in molecular dynamics simulations of the unfolding of helical peptides (reviewed by Brooks and Case⁸⁵).

5.3 Immunogenic Peptides

Peptides can be used as immunogens to elicit antibodies that will in many cases recognize the cognate sequence in the folded protein.⁸⁶ These peptides quite often display conformational preferences for folded conformations in solution.⁸⁷ NMR studies of short peptides have also been used as a convenient way to model the conformations of immunogenic peptides, in systems where the protein immunogens are inaccessible to structure determination, for example, in protein antigens from *Herpes simplex*,⁸⁸ *Plasmodium falciparum*,⁸⁹ and HIV.^{90–92} While no direct structural information can or should be inferred from the conformational preferences seen in these peptides, they can at least give a guide to the design of possible better immunogens.

5.4 Proteins in Pieces and Pieces of Proteins

In an attempt to delineate protein folding initiation sites for different protein structural motifs, several proteins have been examined by dissecting their sequences into a series of peptide fragments and examining the fragments by NMR in aqueous solution. The protein sequences studied include myohemerythrin, a four-helix bundle protein,^{58,93} plastocyanin, a β -sandwich protein,⁹⁴ myoglobin,^{95–99} ubiquitin,¹⁰⁰ BPTI,¹⁰¹ and barnase.^{102,103} The studies on myohemerythrin and plastocyanin each involved a series of overlapping peptides spanning the entire sequence of the protein. It was found that the peptides derived both from the helical segments of myohemerythrin and the interhelix loops have a marked preference toward secondary structure formation in solution, including turn, helix, and nascent helix conformational preferences. By contrast, the peptides from plastocyanin showed very little evidence for

structured forms in solution, except for one turn conformation and a hydrophobic cluster (see below). The results suggest that these two protein structural motifs may require different propensities for formation of local elements of secondary structure to initiate folding, and that there is a prepartitioning of conformational space, dictated by the protein sequence, that is different for the helical and β -sandwich motifs. These results are in agreement with the general trends shown by the folding of proteins of different classes in quench-flow hydrogen exchange experiments (see Section 2.2).

A number of fragments of the myoglobin sequence in the region of the G- and H-helices (see Figure 3) were studied^{97–99} in an attempt to determine which parts of the early intermediate formed in the folding pathway of apomyoglobin (see Section 2.2) were formed first and could therefore be termed the folding initiation sites. The peptides derived from the G- and H-helix portions of the protein exhibited different propensities to fold into helix in solution: the H-helix peptide showed significant helix formation in water solution both by NMR and CD spectroscopy, while the G-helix was not helical in water solution but became strongly helical in TFE solution.⁹⁷ The peptide derived from the sequence between the helices contained a significant population of β -turn, which persisted in fragments of varying lengths⁹⁸ and under a variety of solution conditions. This sequence provides a good candidate for the folding initiation site in the G–H region of apomyoglobin. A 51-residue peptide was synthesized to mimic the G–H helical hairpin in apomyoglobin⁹⁹ and to test whether the helical hairpin portion of the A–G–H intermediate could exist in isolation. The peptide was designed to be monomeric, as it was known that the H-helix peptide, for example, would aggregate to produce four-helix bundle-like structures.⁹⁷ The 51-residue peptide showed almost identical behavior to that of the isolated component peptides: no additional helix was formed, for example, that could have been interpreted as evidence for the formation of the helical hairpin structure. These studies therefore indicated that the formation of the A–G–H molten globule intermediate in the folding of apomyoglobin probably does not involve prior formation of an isolated G–H helical hairpin structure, but rather that the developing structure in the intermediate, initiated by the formation of the G–H turn and the helical structure in the H-helix, is stabilized by tertiary interactions involving the A-helix.

A comparison was made of the secondary structure preferences of two fragments corresponding to different lengths of the N-terminal sequence of ubiquitin and the A-state of ubiquitin in methanol.¹⁰⁰ Although the peptides were unstructured in water solution, the NMR spectra of the three systems showed a number of similarities in methanol solution. The chemical shifts were similar between the shortest peptide, corresponding to residues 1–21 of the protein (the site of a β -hairpin in the native and A-states of the protein), and the analogous regions of the 35-residue peptide (containing the sequence of the β -hairpin and a helix) and the A-state. These results suggest that there are stronger intrinsic structural preferences in the N-terminal half of ubiquitin, which is apparently folded to a greater extent in the A-state than the C-terminal part of the molecule.

Peptide fragments of barnase have been studied by NMR.^{102,103} In an NMR study of a single barnase fragment,¹⁰² the authors conclude by extrapolation from TFE data not shown in the paper that the peptide is helical in water, although

none of the usual determinants of either helix or nascent helix were present in the water spectra shown in the paper. Structures were calculated for several barnase fragments¹⁰³ on the basis of the observation of $d_{\text{NN}}(i, i + 1)$ NOEs alone. No attempt was made in this work to quantitate the population of the folded form, so the significance of the calculated structures is highly questionable. This work, and several similar papers that have now been published, illustrate the difficulty and questionable validity of structure calculations for short, linear peptides in the absence of a thorough understanding of the nature of the peptide conformational ensemble.

5.5 Effect on the Peptide Conformational Ensemble of Receptor/Protein Binding

Peptides interact with larger molecules in many systems, and it appears that a binding interaction with a receptor or protein can cause the conformational ensemble of the peptide to be restricted to the point where it can be said to have a single conformation, at least along part of its length. Binding to the receptor has traditionally been thought to mediate the induced-fit conformation of peptide hormones, which are generally unstructured in solution unless conformationally restricted, and the transferred NOE observed in certain systems where the dissociation rate of the peptide is favorable has been used to infer the bound structure. In systems where the dissociation rate is too slow for the transferred NOE to be observed, a number of NMR experiments have been used to determine the conformation of the bound peptide ligand. For example, NMR methods have been used to investigate the conformation of a peptide, part of the myohemerythrin C-helix (see Section 5.4) bound to an antibody fragment. The peptide, labeled site-specifically with ^{15}N and ^{13}C , was bound to the Fab fragment ($M_r \sim 56\,000$) of an antibody, which had been raised to the C-helix peptide and which also recognized the native folded myohemerythrin protein. The conformation of the bound peptide was investigated by inverse-detected NMR methods.¹⁰⁴ The peptide conformation appears to be helical when bound to the antibody, although it forms only a nascent helix when free in solution. It is encouraging that NMR experiments can be used to gain important information on biological systems as large as Fab-peptide complexes. In another approach, exemplified by the structure determination of a calmodulin-target-peptide complex,¹⁰⁵ isotope-edited multidimensional NMR methods have been applied to a system consisting of ^{13}C , ^{15}N -labeled protein and unlabeled peptide. High-resolution structures were obtained for both the protein and the bound peptide, which was found to fold into a helix upon binding to calmodulin.

6 FUTURE PROSPECTS

Major advances in understanding the molecular mechanisms by which proteins fold into their correct tertiary structures have come from applications of NMR technology to the protein folding problem. With its ability to identify the structures populated in the conformational ensemble of peptide fragments of proteins in aqueous solution under conditions that favor folding, NMR has provided new insights into the probable

events occurring at the earliest stages of the initiation of protein folding. Applications to further proteins and to more complex peptide models of early folding species are to be expected. Relatively new multidimensional NMR experiments now allow complete resonance assignments to be made for unfolded proteins under a variety of denaturing conditions. Such experiments hold exceptional promise for identification of residual structure in denatured proteins and will allow detailed structural characterization of the initial states in the folding process. Application of quenched-flow hydrogen exchange pulse labeling to further protein classes is likely to contribute significantly to our understanding of millisecond timescale folding events, and may ultimately result in a generalized model of the slower steps in the protein folding pathway. Finally, heteronuclear multidimensional NMR studies of stabilized molten globule intermediates are now possible for some proteins and promise to provide important new insights into the three-dimensional structure and dynamics of these states. There can be little doubt that NMR will continue to play a fundamental role in unravelling the protein folding puzzle.

1 INTRODUCTION

The enzymes responsible for the messenger RNA-directed synthesis of proteins are the ribonucleoprotein particles called ribosomes. They range in molecular weight from around 2.5×10^6 to 4.5×10^6 , depending on species. Their interspecific variations notwithstanding, all ribosomes have similar structures and work the same way.¹

There are single copies of each of three RNA molecules in bacterial ribosomes: 23S rRNA ($M_r \sim 10^6$), 16S rRNA ($M_r \sim 0.5 \times 10^6$), and 5S rRNA ($M_r \sim 40\,000$). Mammalian cytoplasmic ribosomes contain four RNAs: 28S rRNA ($M_r \sim 1.6 \times 10^6$), 18S rRNA ($M_r \sim 0.6 \times 10^6$), 5.8S rRNA ($M_r \sim 52\,000$), and 5S rRNA ($M_r \sim 40\,000$). These RNAs are involved in every aspect of ribosome function; interest has never been higher. Nevertheless, remarkably little is known about rRNA conformation at atomic resolution.

2 WHAT CAN rRNA SPECTROSCOPY CONTRIBUTE?

Ribosomal RNAs (rRNAs) are too big to be characterized fully by NMR; even the smallest rRNA, 5S rRNA, is far larger than the largest biological macromolecule whose conformation has been determined so far. Nevertheless, rRNA spectroscopy is not a fool's errand.

Ribosomal RNAs, like all other single-stranded RNAs, satisfy the hydrogen-bonding propensities of their bases by forming hairpin-like structures called stem/loops, many of which have molecular weights below 10 000, and include sequences whose hydrogen-bonding patterns are difficult to diagnose by other means. In addition, many retain their native conformations in isolation, and some bind ribosomal proteins or have other interesting properties. Small RNAs like these are appropriate for spectroscopic investigation.

The parts of large RNAs that fold up into stem/loops or other, more complicated motifs can be identified by comparing the sequences of homologues from many species.² The analysis is based on the proposition that RNAs which perform identical functions must have identical structures despite sequence difference. Experience shows that the secondary structure models that result are accurate. Thus sequences

within large RNAs that might yield to the spectroscopist can be identified in advance.

Some rRNA fragments can be obtained in useful amounts by limited nuclease digestion, but the divide-and-conquer approach to rRNA conformation has come into its own only recently as methods for RNA synthesis have become available.^{3,4} Before that, only two rRNAs were studied: 5S rRNA⁵ and a 16S rRNA sequence called colicin fragment.

3 5S rRNA

The function of 5S rRNA is unknown, but because of its small size and ready availability it has received a lot of attention over the years.⁶

3.1 Counting Imino Protons

The modern era of nucleic acid spectroscopy began in 1971 with the discovery that the imino protons of hydrogen-bonded guanines (Gs) and uracils (Us) resonate between 10 and 15 ppm.^{7,8} The imino protons of exposed Gs and Us exchange too fast to be detected under physiological conditions, and even when they are involved in base pairing, their resonances can only be observed in water, which creates difficulties (see *Water Signal Suppression in NMR of Biomolecules*). Nevertheless, this discovery suggested that nucleic acid secondary structures might some day be determined spectroscopically, which they can.

The goals of the first imino proton investigations were to determine the total numbers of base pairs in RNAs by integrating their downfield spectra, and to use the generic difference in imino proton chemical shifts of AUs and GCs to separate that total into its AU and GC contributions.

5S rRNA was one of the first RNAs analyzed this way. The first downfield integration results were reported for 5S rRNA in 1972, and there have been numerous reports since.^{9–16} A consensus emerged that there are about 35 base pairs in native 5S rRNAs, irrespective of species, but the estimates were never accurate enough to be decisive because 5S imino spectra are poorly resolved, and poorly resolved spectra are hard to integrate.

Resolution of the 5S imino proton spectrum into its AU and GC parts on the basis of chemical shift proved even more problematic, both because of chemical shift range overlap and because 5S rRNAs include non-Watson–Crick base pairs with unusual imino proton chemical shifts. Resolution was achieved only recently using 5S rRNA samples labeled with ¹⁵N at UN3 positions. UN3 resonances were distinguished from GN1 resonances by editing, and five GUs, five AUs, and two unclassifiable, U-containing base pairs were identified in *E. coli* 5S rRNA.¹⁷

3.2 Imino Proton Assignments

About 1978, it was discovered that the NOEs produced by the cross relaxation of imino protons in adjacent base pairs of nucleic acid helices can be detected.^{18–22} Furthermore, it was found that the imino proton resonances of AU pairs have NOE signatures that distinguish them from the imino proton

resonances of GC or GU pairs. This meant that imino proton spectra can be assigned sequentially. The first 5S rRNA imino proton assignments appeared shortly thereafter.

The most thoroughly investigated 5S-related RNA in this regard is a fragment obtained from *E. coli* 5S rRNA by limited RNase A digestion which includes the 3' half of the molecule.²³ It behaves like a domain of the intact molecule.¹⁴ It binds one of the ribosomal proteins that interacts with 5S rRNA, and the spectral perturbations that result are the same as those observed when the same protein binds to intact 5S rRNA.²⁴ The high-frequency (downfield) spectrum of this fragment was completely assigned using the native fragment, mutant variants, and ¹⁵N-labeled samples.^{25–31} A nuclease-resistant fragment from the 5' half of 5S rRNA (*E. coli*) was also isolated, and its high-frequency spectrum was assigned in part.³²

The data confirmed the 5S model obtained phylogenetically, but at the same time demonstrated how poorly the molecule's unpaired loops are understood.³³ In addition, they did not support the class of 5S models that calls for tertiary base-pairing interactions between 5S stem/loops. Recently, imino proton NOEs have been cited as evidence in favor of such a model in the case of a plant 5S rRNA,³⁴ but since no resonances were assigned no conclusion can be drawn.

Instead of concentrating on a single 5S rRNA, Marshall's group studied the imino proton spectra of 5S rRNAs and 5S rRNA fragments from several different species. The existence of the terminal helix of *Bacillus subtilis* 5S rRNA³⁵ and of yeast 5S rRNA was confirmed,³⁶ and many of the imino proton resonances in the 5' arm of wheat germ 5S rRNA were assigned.^{37,38} Studies of fragments of *T. utilis* 5S rRNA resulted in assignments for its 3' half,³⁹ and assignments are also available for imino protons in the 5' half of 5S rRNA of *B. megaterium*.^{40,41}

3.3 Other Observations

Unlike tRNAs, 5S rRNAs include no imino protons that exchange so slowly that solvent exchange can be followed in real time by NMR.^{42,43} The exchange rates of 5S imino protons are reduced significantly when ribosomal proteins bind, however.⁴³ This does not mean that 5S rRNA is 'floppy', however. 5S correlation times have been measured using 5-fluorouracil-labeled samples. Most 5S rRNAs have correlation times greater than 10 ns, which is roughly the rotational correlation time 5S rRNA would have if it were a rigid sphere.^{44,45}

It is also true that 5S rRNA is not as contorted as tRNA. As judged by ³¹P chemical shift, the number of phosphate groups in unusual conformations is much smaller in 5S rRNA than it is in tRNA.^{13,46,47}

3.4 Backbone Assignments and Structural Models

The sequential assignment methodology based on multidimensional NMR, which revolutionized protein spectroscopy in the early 1980s (see *Biological Macromolecules: Structure Determination in Solution*), did not begin having an impact on rRNA spectroscopy until the end of the decade. Marshall's group did one of the first sequential assignment studies in connection with their analysis of conformational ambiguity in a

wheat germ 5S fragment that runs from C26 to G51.^{40,48,49} A structural model was not produced, however.

A three-dimensional model did result, however, from the study of a 22-residue fragment from *E. coli* 5S rRNA that includes the molecule's terminal helix, helix I.⁵⁰ Helix I is an A-type RNA helix, as expected, but there is a considerable conformational variation from one base pair to the next which seems to be due to purine–purine base stacking; the biggest excursion occurs at the GU at the top of the helix. 'Distortions' of this kind account for the tendency of GU imino protons to give NOEs to the imino protons of base pairs on the 3' side of the G, but not to those on the 5' side.

About the same time, Tinoco's group examined two synthetic oligonucleotides whose sequences were based on that of loop E from *Xenopus laevis* 5S rRNA (U72–C78, G97–A102). Following a study of a mutant sequence, whose conformation turned out to be grossly abnormal,^{51,52} the wild type sequence was examined.⁵³ There is no reason to talk about the model that emerged here because the loop E motif—quite remarkably—also appears in the sarcin/ricin loop, which is discussed below.

4 COLICIN FRAGMENT

Colicin E3 is a bactericidal protein that inactivates ribosomes by cleaving 16S rRNA 49 bases in from its 3' end. The fragment released—colicin fragment—includes a nine base pair stem which is capped with a GGAA loop. The first G in the loop is methylated at the N2 position, and both As are dimethylated at N6. Ribosomes in which the As are unmethylated are resistant to kasugamycin, an antibiotic that inhibits initiation.⁵⁴

The existence of the nine base pair stem in colicin fragment has been proven spectroscopically and its imino proton spectrum assigned.⁵⁵ Removal of the methyl groups from As in the loop perturbs the base pairs at the top of the stem somewhat.⁵⁶ The effect of methylation has also been examined in *B. stearothermophilus*. Three forms of its colicin fragment were studied: the normal (methylated) form, the kasugamycin-resistant (only the G methylated) form, and a synthetic form, which is totally unmethylated. Methylation has only a small effect on the high-frequency spectra of these molecules, but it does affect stem/loop stability; the fewer the number of methyl groups on the loop, the more stable the stem.⁵⁶

Colicin fragment samples have been prepared carrying ¹³C-labeled methyl groups.⁵⁷ Carbon-13 data show that the methylated exocyclic nitrogen of free *N*-6-dimethyladenosine rotates so rapidly that its methyl groups are magnetically equivalent, but when it is part of the colicin loop the rotation is hindered enough to make its methyl groups distinguishable.

The imino proton and nonexchangeable proton spectra of complexes between colicin fragment and initiation factor IF-3 have also been examined.⁵⁸ There are clear indications that a specific complex forms, but it has not been characterized further.

5 SYNTHETIC FRAGMENTS FROM THE LARGE rRNAs

Structures have been obtained recently for synthetic rRNA fragments containing two types of tetraloops (four base loops)

and the sarcin/ricin loop. The tetraloops characterized—the UNCG type and the GNRA type—are the ones most common in rRNAs.⁵⁹ ['N' means any base and 'R' means purine.] Helical stems terminated by UNCG tetraloops are unusually stable.⁶⁰ All 23S-like rRNAs include a sarcin/ricin loop which plays a critical role in the elongation phase of protein synthesis.

5.1 rRNA Tetraloops

In the late 1980s, Tinoco's group determined the conformation of a synthetic stem/loop that is terminated with a UUCG tetraloop.^{61,62} The oligonucleotide's proton spectrum was almost completely assigned, and a conformational model resulted from the analysis of its NOEs and coupling constants. The key to the structure is a reverse-wobble base pair (UO2–GN3, UN3–GO2) between the 5' U of the loop and its 3' G. The distance between the phosphates of the two strands is so reduced by that pairing that it can be spanned by two C2'-*endo* residues. Additional stabilization is provided by a hydrogen bond involving the amino group of the tetraloop C

with an oxygen of the phosphate group between the two Us, and by base stacking.

The elegant economy of means evident in UNCG tetraloops is also manifest in GNRA tetraloops. Two such tetraloops have been examined: GCAA and GAAA.⁶³ They are essentially the same. The reverse-wobble GUs in UNCG tetraloops are replaced by (AN6–GN3, AN7–GN2) GA pairs. Like reverse-wobble GUs, these AG pairs close the stem to the point that the remaining gap can be spanned by two C2'-*endo* residues. Additional stability is provided by a hydrogen bond between the amino group of the G and an oxygen that is part of the phosphate joining the (last) two As. All of the bases in the GAAA tetraloop stack neatly on their neighbors. The C residue in the GCAA version of the loop appears not to stack. The loop at the top of the structure shown in Figure 1 is a GNRA tetraloop.

The destabilizing effect of methylation on the colicin fragment stem/loop mentioned earlier is easy to rationalize. The colicin loop, GGAA, is a GNRA tetraloop. Dimethylation of N6 of the final A should prevent the formation of that loop's

Figure 1 A stereo drawing of the sarcin/ricin loop. The mammalian form of the sarcin/ricin loop is shown in the conformation determined for it by NMR.⁶⁷ (Drawing donated by Dr. A. Szewczak, Yale University)

critical GA, which should destabilize it. Methylation at the N-2 position of the G in the GA pair should also be damaging, but less so since one of the two possible rotamers places the methyl in an innocuous position.

5.2 The Sarcin/Ricin Loop

The sarcin/ricin loop is the most recent addition to the list of fully characterized rRNA fragments. All 23S-like rRNAs have a loop that includes a 12-base sequence that is the longest invariant sequence in rRNAs. It is attacked by two protein toxins, α -sarcin and ricin, which kill eukaryotic cells by cleaving covalent bonds in the invariant sequence. These cleavages inhibit the interaction of ribosomes with elongation factors during protein synthesis, which is lethal for the cells in question.⁶⁴

A 29-nucleotide sequence, that includes the entire sarcin/ricin loop in its mammalian form, has been analyzed. All its ³¹P and nearly all its ¹H resonances were assigned, and a model built based on NOEs and coupling constants (Figure 1).⁶⁵ The top of the loop, where it is attacked by toxins, is a GNRA tetraloop motif as already indicated. Immediately below that, the sarcin/ricin loop contains a loop E motif. Thus this structure embodies the rRNA spectroscopist's fondest hope, that it will be possible to produce accurate models for the conformations of large RNAs by assembling them from small pieces whose conformations are already understood.

Working from top to bottom in Figure 1, the loop E motif begins with a conventional GC base pair (C13–G18) below which is a GA pair (A12N7–G19N2, A12N6–G19N3), and then a reversed-Hoogsteen AU (A20N6–U11O2, A20N7–U11N3). This juxtaposition positions G10 so that it can extend across the major groove; it is a bulged base. The backbone distortions that result are resolved by a severe kink on the 5' side of the loop, which is stabilized by a symmetric AA pair (A9–A21). Two pyrimidine–pyrimidine pairs follow before Watson–Crick pairing resumes. The bulged G and the bases that surround it are in the same conformation as the bases in loop E in eukaryotic 5S RNA.

6 OTHER rRNA STUDIES

The downfield spectrum of 5.8S rRNA has been examined, and some of its resonances assigned.⁶⁶ The relaxation properties of ³¹P resonances in intact ribosomes and ribosomes partially degraded with RNase A have been measured. There is reason to believe that rRNA phosphate groups are less mobile in intact ribosomes than they are in free RNA.⁶⁷

1 INTRODUCTION: HISTORY

RNA, in general, and transfer RNA (tRNA) in particular, have played important historical roles in the development of NMR techniques for the study of both RNA and DNA structure/function relationships. However, the small numbers of crystal structures of tRNAs, yeast tRNA^{Phe} being the first,¹ and tRNAs with their cognate aminoacyl-tRNA synthetases, remain the largest, completely resolved nucleic acid structures. Each tRNA is composed of some 76 nucleosides connected by phosphodiester bonds and, thus, is of a molecular weight approximating 26 000 Da (Figure 1). In addition, as many as 25% of the nucleosides are enzymatically modified after the molecule has been biosynthesized, a process designated posttranscriptional modification.² The tRNA is folded into a 'cloverleaf' secondary structure (Figure 1) held together by some 24 Watson-Crick hydrogen bonds between complementary bases (A·U and G·C). An 'L-shaped' tertiary structure is maintained by some six additional, and noncanonical, H-bonds and includes four internal sites where metal ions (Mg²⁺) bind tightly (Figure 1). Therefore, the complete determination of a tRNA's three-dimensional structure in solution becomes a formidable task requiring innovative NMR methods.

Soon after publication of the crystallographic structure of yeast tRNA^{Phe} (Figure 1),¹ identification of the 'low field', H₂O-exchangeable, imino proton resonances that arose from the secondary and tertiary structure hydrogen bonding within native tRNAs became an obviously important NMR approach to understanding the solution structure of tRNA and other nucleic acids.³ The first ¹H NMR spectra of tRNA were published in 1971.⁴ In that paper, the highest frequency proton resonances of a tRNA spectrum, 10–15 ppm, were identified as those from the H-bonded imino protons, one from each of the secondary and tertiary structure H bonds. Because the modified nucleosides tend to reside in the loops of the clover leaf structure, some of the most interesting

of the H bonds are those in which the minor, or modified bases participate in creating tertiary structure interactions and chemistry, including metal ion binding sites, important to tRNA function. The methods to identify unambiguously the secondary and tertiary imino base paired protons in tRNA required the development of new technologies that were completed a decade later. Now the well-established techniques of two-dimensional homonuclear NOE, NOESY, and the ¹⁵N-edited NOESY in H₂O are used regularly for both RNA and DNA analyses.⁵ Carbon-bound, proton resonances from the base ring carbons provide additional information about tRNA conformation.⁶ Carbon-bound protons of modifications are useful in the unambiguous identification of the nucleoside residue of which they are a part. Of particular interest are the assignments of individual signals from the carbon-bound protons of each ribose moiety, which would lead to identification of each nucleoside's spin system, sugar pucker and glycosidic (base to ribose) bond angle when combined with information on the individual bases and their modifications. The rotation around the 3'–4' and 4'–5' bonds of each ribose are part of the tRNA's (or for that matter all nucleic acids') backbone, and thus knowledge of sugar pucker (from scalar couplings) leads to the resolution of backbone torsion angles. (See *Vicinal Coupling Constants and Conformation of Biomolecules*.) This information plus identification of individual ³¹P resonances and *J*(H,P) couplings, for the 3'- and 5'-associated phosphates (see *Nucleic Acids: Phosphorus-31 NMR*), has the potential for characterizing the tRNA backbone. Because of their involvement in unique tertiary structure interactions, the identification of the various modified nucleoside spin systems is particularly important.^{2,3} However, the complete signal assignment of a tRNA molecule has yet to be accomplished.

The first heteronuclear experiment, that of natural abundance ¹³C, was accomplished in 1972.⁷ In general, ¹³C spectra for complex molecules tend to be more resolved than ¹H spectra. These spectra also provide valuable information for the determination of molecular dynamics. However, the major drawback to natural abundance ¹³C spectroscopy is that some of the most interesting resonances, that of the modified nucleosides, are the weakest. The great advantage of heteronuclear enrichment of specific atoms and nucleosides for signal assignments, and for the analysis of structure and dynamics, was realized early with the 1975 report of a ¹³C enrichment, in vivo, of all methyl group modifications of *E. coli* tRNAs.⁸

2 APPROACHES TO MODIFIED NUCLEOSIDE HETERONUCLEAR MAGNETIC RESONANCE AND DYNAMICS

Site specific, natural, structure/function NMR probes of tRNA that neither disrupt structure nor function but occur at multiple locations are essential because of tRNA's size and the size of the nucleic acids and proteins with which it interacts.⁹ Methyl and methylene ¹³C-enrichment is applicable to the vast majority of the 80+ known modifications. In addition, ¹³C-enrichment of modified base ring carbons, such as the 2-positions of adenosine for methyl-2-adenosine (m²A) and methylthio-2-adenosine (ms²A), and thio-2-uridine (s²U), offer additional information by having distinctly different chemical

Figure 1 Structures of a modified mononucleoside and modified nucleoside-containing trimer, heptadecamer and yeast tRNA^{Phe}. The structure of yeast tRNA^{Phe}, derived from X-ray crystallography,¹ is shown with the backbone as a ribbon. The amino acid accepting, 3'-terminus is designated AA; the anticodon stem and loop in green is designated AC. There are four tight metal ion binding sites, but only the one occurring in the anticodon is shown because of its relevance to the studies described here. Below this structure is its nucleoside sequence drawn in the 'cloverleaf' depiction of the secondary structure base pairings. A heptadecamer DNA analog of the tRNA^{Phe} anticodon stem and loop is also drawn with the green ribbon backbone. The mononucleoside is the anticodon wobble position nucleoside s²mm⁵U; the trimer, Dp-acp³Up-A, occurs in the D loops of tRNAs for Asn and Val

shifts from that of the unmodified nucleosides, A and U. Peak widths for the ¹³C₂s for folded tRNA were determined largely by chemical shift nonequivalence.¹⁰ Measurements of *T*₂ for the specifically enriched carbons in tRNA suggested that the intrinsic linewidths were between 2–4 Hz for the C-2 of the pyrimidines, whereas adenine with a directly bonded proton exhibited a 40 Hz linewidth. Consideration of dipolar relaxation and chemical shift anisotropy (CSA) led to a calculated rotational correlation time of $1.6 \pm 0.4 \times 10^{-8}$ s for the adenosines.

Carbon-13 enrichment of methyl groups led to the first resolution of single carbon resonances in a nucleic acid and proved that methyl probes were sensitive to changes in local structure, a requisite criterion for ¹³C NMR of tRNA to

be a useful tool.^{11,12} For instance, multiple peaks for the ¹³C-enriched methyl groups of T₅₄ (methyl-5-U) in *E. coli* tRNA^{Phe} and tRNA^{Tyr} and ribose 2'-O-methylated G₁₇ of tRNA^{Tyr} indicated multiple structural forms that coalesced in the presence of Mg²⁺, whereas tRNAs specific for Cys and Ser existed in only one major conformation throughout their structures, even in the absence of Mg²⁺.¹³ Proton NMR spectra of the ¹³CH₃-enriched tRNAs exhibited the expected resonance splittings with *J*(C,H) values of 130–145 Hz for all the methyl resonances. Values of spin-lattice relaxation times, NOEs, and linewidths for the ¹³CH₃ carbons in the presence of Mg²⁺ were utilized for determining rotational reorientation correlation times. The different tRNAs had

Figure 2 ^1H -detected, ^1H - ^{13}C HMQC of $^{13}\text{CH}_3$ -enriched native yeast tRNA^{Phe}. Data were acquired on a 500 MHz GE-Omega spectrometer at 25 °C in phase-sensitive mode; 1024 complex points were used in the ^1H dimension and 256 blocks were collected. Data were processed using Felix (D. Hare Software) with a line broadening of 2 Hz in the ^1H dimension and a Kaiser window function in the ^{13}C dimension. Data were zero filled in the F_1 dimension to 512 complex points

significantly different (by factors of two) apparent overall rotational correlation times (τ_R). Since the molecules are approximately the same in molecular weight, τ_R probably reflects true differences in the motional capabilities of large sections of the different tRNAs. Internal correlation times for the methyl groups on axis (τ_i) varied between 0.4–1.6 ps for the methyl of T, and between 0.8–2.0 ps for the methyl of methylthio-2-isopentenyl-6-adenosine ($\text{ms}^2\text{i}^6\text{A}$) of four different tRNAs. Enough differences in spectra, relaxation rates, NOEs, and calculated τ_R and τ_i values of the tRNAs were found to conclude that specific differences in structure and dynamics were probed by each of the modified nucleosides.¹³

Yeast tRNA (Figure 1), having many more modified nucleosides than *E. coli* tRNAs and having methyl groups located in various positions throughout the structure, provides a considerable advantage to probing tRNA structure, chemistry, and dynamics with $^{13}\text{CH}_3$ -enrichment.^{14,15} Twelve resolved, prominent and readily assigned $^{13}\text{CH}_3$ -enriched resonances are seen in the ^{13}C spectrum of purified yeast tRNA^{Phe} (Figure 2). The methyl resonances have a wide chemical shift dispersion between 10 and 60 ppm (Figure 2). Half of the signals are from modified nucleosides of the anticodon domain of the molecule (Figure 1). The assignments of methyl and methylene peaks in tRNA ^1H NMR spectra have relied on thermal melting studies where resonances are followed from high temperature (unfolded) to low temperature (folded). This method breaks down when peaks undergo slow chemical exchange dynamics, disappearing from one position and reappearing at another.¹⁶ In addition, the high temperature and extended acquisition times can lead to the degradation of the molecule and to the formation of unnatural, but stable, intermediate tertiary structures. The introduction of $^{13}\text{CH}_3$ -enrichment permits an alternative method to signal assignments based on

scalar coupling of ^{13}C and ^1H and resulted in the first application of carbon–proton correlation spectroscopy to a native nucleic acid, yeast, and *E. coli* tRNA^{Phe}.¹⁵ By associating the specifically $^{13}\text{CH}_3$ -enrichment to the ^1H s, via a heteronuclear ^1H -detected multiple quantum coherence (HMQC) experiment, complete assignments can be made readily even in the presence of a H_2O ('jump and return') or residual H_2O signal (with suppression by presaturation) that would normally conceal the ^1H signals of some of the modifications (Figure 2).

Comparison of carbon-methyl chemical shifts of the *N*-methylated, $^{13}\text{CH}_3$ -enriched m^1A_{58} and m^7G_{46} in yeast tRNA^{Phe} with that of the mononucleosides m^1A and m^7G under various conditions provided a means by which the chemical character of these nucleosides could be explored within the native tRNA structure.¹⁵ The methyl group carbon chemical shifts of the two nucleosides in the tRNA were indicative of fully protonated and positively charged chemical species. The modified nucleosides were protonated through tertiary structure H bonding, resulting in two full positive charges within the native tRNA. Interaction of the tRNA with other macromolecules could break these specific H bonds, removing the charges, and thus, prepare tRNA for the next step in translation.

Yeast tRNA^{Phe} $^{13}\text{CH}_3$ groups have been used as probes of internal dynamics at specific locations.¹⁷ Values of ^{13}C T_1 and NOE are determined at various magnetic field strengths and used to extract generalized order parameters (S^2) and effective correlation times (τ_e) for the internal motion of the C–H internuclear vectors. For all methyl groups, S^2 compared favorably with the value of 0.111 predicted for a rapidly spinning methyl group rigidly mounted on a spherical macromolecule. However, values of τ_e , 4–16 ps, were generally shorter than that measured for the methyls of amino acids in proteins! Somewhat surprising was the fact that the methyl esters at the end of a long methionine-derived side chain attached to the tricyclic nucleoside wyosine (Y_{37}), a hypermodification of G_{37} 3'-adjacent to the anticodon (Figure 1), had order parameters (S^2), only 25% less than that of a methyl directly bonded to the same base ring structure. The side chain may have stabilizing interactions within the anticodon domain of the tRNA. If motion of the methyl group axis were described as random diffusion within a cone, the values of the order parameter S_{ax}^2 corresponded to cone semiangles of 11° to 37°.¹⁷ This model-free approach to the analyses of the $^{13}\text{CH}_3$ data indicated that the anticodon domain was the most highly motion-restricted portion of tRNA, a conclusion since confirmed by other NMR techniques and other methods.¹⁷

In ^{13}C spectra of tRNA^{Phe} taken at 75.5 MHz with proton decoupling gated off during acquisition, unequal linewidths are observed for individual transitions in the CH_3 quartets. The most important mechanism contributing to this differential line broadening is probably interference between the dipolar and CSA relaxation mechanisms.¹⁷ The differential line broadening is not the same for every methyl group. The mathematical formalism of this phenomenon can serve as an additional means by which the motional parameters of tRNA may be calculated and compared with that derived from T_1 and NOE measurements.

3 MONOMERS TO RNA DOMAINS: NMR SOLUTION CONDITIONS, IMPORTANCE, AND DIFFICULTIES

The NMR investigations of modified nucleoside contributions to the chemistry, structure, and dynamics of the complete tRNA molecule, as summarized above, although instructive and informative, reveal limited information because of the large size of the molecule. However, one approach that is worth reiterating is the comparison of modified nucleoside conformation derived from the NMR of an RNA oligomer with data from the individual modified mononucleoside taken under identical solution and temperature conditions, as with the analyses of m^1A and m^7G . The contributions of the modified nucleosides to the RNA can be determined by NMR, along with the effects of the polymerization on the nucleoside conformation and chemistry. Of particular interest are the modified uridines; thio-2-methylaminomethyl-5-uridine (s^2mm^5U) is depicted in Figure 1. The s^2Us with various 5-position derivatizations occur at the anticodon ‘wobble’ position 34 in tRNAs for Glu, Gln, and Lys. Proton and carbon NMR analyses of the s^2U derivatives showed that the thio-substituted carbonyl restricts the nucleoside conformation and dynamics of the mononucleoside, no matter the character of the 5-position derivative. The highly restricted conformation is retained in dimers and affects the torsion angles of the 3′-phosphodiester bond investigated through 1H – ^{31}P and ^{13}C – ^{31}P correlation spectroscopy.¹⁸ Because the restrained s^2U conformation restricts these tRNAs to binding codons ending in A, i.e. no ‘wobble’, a modified wobble hypothesis has been presented.¹⁹

One of the most common of the modified uridines is the hydrophobic dihydrouridine, D, which occurs in loop I of almost all tRNAs, sometimes adjacent to the hydrophilic 3-[3-(*S*)-amino-3-carboxypropyl]uridine, acp^3U , in the sequence $Dp-acp^3Up-A$ (Figure 1).²⁰ NMR of this trimer illustrates how the perceived complexity of its proton spectrum can be approached successfully with heteronuclear and homonuclear two-dimensional spectroscopy. Signal assignments of the modified and unmodified nucleoside ribose protons, especially the 5′ and 5″ protons, within RNA oligomers can be difficult because of tRNA size and the size of the nucleic acids and proteins with which it interacts. However, the 1H – ^{13}C HMQC of $Dp-acp^3Up-A$ depicted in Figure 3 illustrates the relative ease with which these assignments can be made. With oligomers of the size of $Dp-acp^3Up-A$, there can be a difference in the time-dependence of the NOE for the trimer in aqueous solvent versus DMSO. The correlation time of $Dp-acp^3Up-A$ in D_2O was such that $\omega\tau_c \approx 1$, so that NOEs tended toward zero. The cross relaxation rate in DMSO was about 20-fold that in D_2O . Therefore, to aid in the determination of NOE cross peaks in D_2O , a ROESY experiment is preferred (Figure 4). The NOE observed from the 1H -6 proton to the ribose ring can be used as a marker to decide whether the predominant conformation is *syn* or *anti*. Thus, when the dipolar correlation from H-6 to H-2′ is stronger than that from H-6–H-1′, the *anti* conformation is indicated. When the relative intensity of the correlations is reversed, the *syn* conformation is indicated. Both cross peaks were observed, indicating the presence of both *syn* and *anti* conformations, but with *anti* dominating. The solution conditions of these studies have to be strictly controlled because many modified nucleosides, such as acp^3U

Figure 3 1H -detected, 1H – ^{13}C HMQC of $Dp-acp^3Up-A$. Data were acquired and processed as explained in the legend to Figure 2

and s^2mm^5U , bind metal ions. For example, when part of an oligomer or RNA domain acp^3U will bind metal ions, Mg^{2+} in particular, this changes the chemical shifts and scalar couplings, and alters the conformation of the oligomer (unpublished results).

Although modified nucleoside-containing small oligomers have some of the properties of their sequences within tRNA, they are not functionally recognized domains of the tRNA molecule. One approach to understanding the contributions of single modifications is the NMR spectral comparison of fully modified tRNA species with that derived from a bacterial or yeast mutant strain lacking a particular nucleoside modification enzyme.²¹ This approach is limited by the small number of mutant strains. In order to arrive at a complete structural determination of functional domains of tRNA, and for that matter other RNAs and DNA that contain modified nucleosides, we developed synthetic methods to complement the NMR approach. The anticodon stem/loop domain of yeast tRNA^{Phe}, tRNA^{Phe}_{AC} (Figure 1), being a physically separate entity of the crystal structure,¹ highly modified with five modified nucleosides out of 17, of moderate size at 5400 Da, and functionally recognized by both yeast phenylalanyl-tRNA synthetase and the ribosome, met all the criteria of a domain. The synthesis of this molecule with one to four modified nucleosides was achieved in good yield by the now standard automated chemical synthesis of RNA from 2′-*O*-silyl-*t*-butyl-5′-*O*-dimethyltritylnucleoside-3′-phosphoramidites. Some of the modified nucleosides required additional protection (unpublished results).

4 HOMONUCLEAR 1D AND 2D NMR OF MODIFIED NUCLEOSIDE-CONTAINING DOMAINS

The tRNA^{Phe}_{AC} structure modified with a $d(m^5C_{14})$ at the position analogous to m^5C_{40} of native tRNA^{Phe}, has been investigated by 1H NMR.²² The high-frequency portion of the spectrum, that included the H_2O -exchangeable, base

Figure 4 ROESY of Dp-acp³Up-A. Data were acquired on a 500 MHz GE-Omega spectrometer at 20°C in phase-sensitive mode with 1024 complex points and a 300 ms mixing time. Data from 256 blocks were processed with Felix with a 15° phase-shifted sine-bell window function in both dimensions and were zero filled in the F_1 dimension to 1024 complex points. The cross-peak annotations within the figure denote NOEs between the proton signal on the F_2 , first, to that on the F_1 , second

paired imino proton signals, was assigned by NOE difference spectroscopy. The results clearly indicated that, in the presence of Mg^{2+} , the molecule had a double stranded stem of five base pairs and two additional base pairs across what was a seven-membered loop in the unmodified tRNA^{Phe}_{AC}.²² Methylation of cytidine in the yeast tRNA^{Phe}_{AC} enables the molecule to form more than one conformation through a process regulated by Mg^{2+} concentration. Thus, the simplest of the posttranscriptional modifications of tRNA, a methylation, is involved in a somewhat distant, internal-site Mg^{2+} binding and stabilization of the tRNA structure, especially that of the anticodon stem and loop. However, with the introduction of a second modification, m¹G the precursor to Y, at the site of Y₃₇, one of the two cross loop, canonical base pairs was broken and a more open loop resulted. Nonexchangeable proton signals are determined by double quantum filtered COSY (DQF-COSY),

HOHAHA and NOESY. (A detailed description of the NMR techniques directed at determination of tRNA anticodon structure, dynamics and function is available.²³)

In order to evaluate the importance of the RNA 2'-OH to RNA structure relative to modifications, we have synthesized and analyzed modified nucleoside-containing DNA analogs of the tRNA^{Phe} anticodon stem and loop. The NOESY (Figure 5), DQF-COSY, and HOHAHA spectra of the DNA 17mer have provided sufficient information to begin modeling the structure with distance and torsion angle constraints (Figure 1). Almost all of the molecule's nucleosides have the B-form DNA 2'-*endo* conformation obtained from the ribose scalar couplings, with the exception of those around the Mg^{2+} binding site at the bottom of the stem. Aromatic to ribose NOEs showed that all nucleoside glycosidic bonds are *anti* with the one possible exception of the bulged A₁₂ in the loop before the 3'-side of the stem. Similar to the tRNA^{Phe}_{AC}, the DNA analog has a 3'-stack easily recognized by following the trace of NOEs from the anticodon to the 3'-terminal nucleoside (Figure 5).

5 THE FUTURE OF MODIFIED NUCLEOSIDE NMR

The contributions of the naturally occurring modified nucleosides to the chemistry, structure, and function of RNAs and DNA cannot be ignored. As demonstrated here, even the simplest of modified nucleosides, the methylated and thio-substituted, can dramatically affect the chemistry and structure in ways that are detected and analyzed by NMR. Therefore, why not use modified nucleosides as site-specific NMR probes of structure and function? Modified nucleosides create sites of positive (quaternary nitrogens) and negative (carboxylic acid derivatives) charges that can be assessed by ¹³C and ¹⁵N NMR. Metal ion binding sites are created indirectly through a modified nucleoside alteration in backbone, m⁵C, and directly by providing ligands, acp³U, which can be detected by chemical shift and scalar coupling changes during metal ion titrations. The metal ion ligands would conceivably be detected by changes in chemical shift and linewidth during paramagnetic ion replacements. Modified nucleosides produce restricted local motion (through higher conformational energy barriers) that are determined by heteronuclear NMR. The selected hydrogen bonding produced by modified nucleosides (by restricting nucleoside conformation, and by negating either Watson-Crick or noncanonical base pairing) is detected with analysis of the H₂O-exchangeable imino proton region of the spectrum of modified RNA in comparison to that of the unmodified RNA.

At present there are only two synthetic pathways to the production of site-specific, modified nucleoside-containing RNA in quantities for NMR: isolation and purification of *in vivo* synthesized species, or automated chemical synthesis. *In vitro* T7 transcription, though capable of yielding large amounts of RNA for NMR, neither produces site-selectively modified, nor site-selective stable isotope enrichment of the RNA. The *in vivo* production is effective for obtaining the fully modified, native RNA with ¹³C and ¹⁵N labeling via precursors of the modifications. Unfortunately, most modified RNA species of interest are only a few percent of the total RNA. Overproduction from a cloned gene usually leads to a completely unmodified, or multiple isomers of partially modified RNA.

Figure 5 NOESY of the m^5C -containing anticodon stem loop domain of $tDNA^{Phe}$. The anticodon stem loop-analog domain of yeast $tRNA^{Phe}$ was synthesized with $d(m^5C)$ at the location analogous to m^5C in the $tRNA$.²² Data were acquired on a 500MHz GE-Omega spectrometer in the phase-sensitive mode at 10°C with a mixing time of 200ms; 256 blocks were collected. Data were processed under the same conditions as Figure 4

Automated chemical synthesis has the advantage of a controlled approach to the synthesis of NMR quantities and to the introduction of one or more modified nucleosides, native or nonnative, at the natural residues or other positions. It also has the potential for the introduction of any modified nucleosides, ribo- or deoxyribo-, at any position in the nucleic acid, thus providing an avenue to chimeric RNA/DNA oligomers. Finally, through the chemical synthesis of isotope-enriched bases and sugars of modified and unmodified nucleoside phosphoramidites, heteronuclear two-dimensional and isotope-edited multidimensional NMR approaches to modified nucleoside contributions to nucleic acid chemistry, structure, and dynamics will be attained.

1 INTRODUCTION

Carbohydrates, and in particular carbohydrates bound to proteins, present a formidable challenge in structural characterization of biologically important systems. Nuclear Magnetic Resonance has played, and will continue to play, a pivotal role in meeting this challenge. We hope to briefly review this role in what follows, but the reasons behind the importance of NMR in these applications offers equally interesting insight into the experiments used and how these experiments will evolve in the future. We hope to offer some of this insight as well.

Aside from their importance in the biosynthesis and degradation of polysaccharides and glycoconjugates, protein-carbohydrate interactions play key roles in intracellular targeting and trafficking of glycoproteins, and in modulating communication of cells with each other and with their environment.^{1,2} Biochemical and physiological processes mediated by these interactions include control of glycoprotein folding and clearance from circulation, selective adhesion and aggregation of specific cell types, developmentally regulated guidance of cell migration and organization, chemotaxis, signaling by hormones and transcription factors, immune and autoimmune responses, sperm-egg recognition, and maintenance of central and peripheral nerve cell myelination.¹⁻⁹ Add to this the myriad of pathogens that use similar interactions in the course of invading their hosts, and one begins to gain an appreciation for the potential importance of understanding the structural basis for protein-carbohydrate interactions. We cannot review many examples here, but the interaction of selectins with cell surface oligosaccharides can serve to illustrate the process.¹⁰⁻¹² Selectins are proteins found on the surface of endothelial cells, leukocytes, and platelets. Endothelial selectins are expressed in response to injury and initiate recruitment of leucocytes to these sites by interacting with oligosaccharides attached to glycoproteins on the surface of leucocytes to slow their passage to a point of "rolling" along the injured surface. Other selectins serve to extend this interaction to the point where leucocytes invade the injured tissue. This is normally a desirable process, but one that also goes awry in events such as rheumatoid arthritis and reperfusion

injury following stroke or other ischemic episodes. Development of drugs that can combat these undesirable events is one activity that benefits from a structural understanding of the interactions of proteins with carbohydrates. There are other examples, many of which are detailed in a collection of articles in a recent issue of the journal *Science*.¹³

The reason that structural characterization of carbohydrate-protein interactions is challenging begins with structural diversity of carbohydrates themselves. Building blocks (or residues) that dominate the N-linked oligosaccharides of glycoproteins are approximately 6 in number. This is only slightly larger than the number of nucleotide building blocks that encode genetic information in DNA. However, unlike the linear nucleic acid polymers (or peptide polymers), carbohydrate oligomers can be branched, and linkages can be made through four different residue hydroxyls with two possible forms at the anomeric center (alpha and beta). Given this additional variability one reaches an astounding 48,384 different possible primary structures for just trisaccharides. Of course, not all of these are produced biosynthetically, but we have also not counted O-linked oligosaccharides of proteins, the oligosaccharides of glycolipids, or the oligosaccharides in carbohydrate polymers such as heparin, plant cell walls, and outer membranes of gram negative bacteria. Add to this the fact that glycoproteins are estimated to constitute approximately half of all proteins, and one begins to appreciate the magnitude of the analytical challenge. Examples of oligosaccharides taken from parts of N-linked glycosides are given in Figure 1.

The reason that NMR has proven so useful in characterizing primary structures of molecules such as those described above is that it requires only the presence of magnetically active nuclei; carbohydrates have abundant ¹H and ¹³C sites. Carbohydrates are also devoid of other types of convenient spectroscopic markers. NMR has also provided a convenient source of conformational information. Except for 1-6 linkages, common glycosidic linkages between sugar residues have two torsional variables, ϕ and φ , much like the linkages between peptide residues in proteins. As can be seen in Figure 1(b), close approach of proton pairs across the glycosidic linkage can allow the detection of NOEs that provide both information on the linkage site and a distance constraint on the glycosidic torsion angles. More recently measurement of three bond scalar couplings between the anomeric proton and the transglycosidic carbon or transglycosidic proton and anomeric carbon have allowed a more robust method of identification of linkage position and torsional constraint.¹⁴ A number of reviews presenting approaches to the determination of oligosaccharide structure in solution exist.^{15,16}

Despite the promise of contributions that NMR can make, there are also some challenges. Carbohydrates are not very diverse in terms of functional groups, being composed primarily of hydroxylated methines. This leads to a concentration of resonances from most non-exchangeable hydrogens 3-5 ppm downfield of the TMS resonance. The availability of high field NMR spectrometers and multidimensional heteronuclear editing methods has helped immensely in dealing with the resulting resolution problem. Flexibility about the glycosidic bonds poses another problem. Except in the cases of sterically crowded linkages, measurements that relate to conformational preferences really reflect an average over a distribution of conformers. Combining measurements that average with different weighting of conformational states, such as the NOE and three

Figure 1 Schematic representation of two N-linked glycosides (a) Sialyl Lewis-X terminated and (b) a trimannoside with the individual pyranose units as labeled in the figure. Some of the intra and inter residue NOEs observed in the trimannoside structure and relevant to the text are depicted in the figure. The glycosidic torsional angles are denoted by ϕ , ψ and ω

bond scalar couplings, as well as analyzing spin relaxation measurements, have offered insight into the nature of these averages.

The issue of an oligosaccharide's conformation, as it exists in a protein binding site, offers a challenge of its own. Many of the proteins that bind oligosaccharides are large, and with NMR line widths scaling up with effective molecular weight, direct observation of tightly bound oligosaccharide ligands is difficult. In a few cases difficulties have been surmounted through the use of isotope enrichment. ¹³C enriched oligosaccharides have become available through both synthetic routes^{17–19} and the use of oligosaccharides produced by bacteria as capsular polysaccharides.^{20,21} However, by far the most common solution is to collect spectra on oligosaccharides that exchange rapidly between bound and free states and in the process average narrow line widths of the free state with the broad line widths of the bound state to achieve an acceptable compromise. Fortunately, many oligosaccharide binding proteins exhibit rather weak binding from the point of view of isolated sites and exchange tends to be rapid ($>100\text{ s}^{-1}$); they achieve the high effective binding affinities needed for many biological actions by cooperating in multimeric aggregates.

Scalar coupling information averages with equal weights between bound and free states, resulting in an average coupling that contains too little information about the bound state to be useful. However, NOEs average with a weighting roughly proportional to the molecular weights of the free and complexed forms. This arises because the cross relaxation leading to NOEs has an efficiency that, for large systems, scales up in proportion to molecular weight. For a 80 kDa protein binding an 800 Da oligosaccharide this means that the bound state NOE will dominate by a factor of ten even if the free oligosaccharide is in ten fold excess. Domination can

be even greater than this as the product of correlation time for the free molecule, and the Larmor frequency at which the spectrometer operates, approaches one. NOEs pass through zero as they change from positive to negative in going from the small molecule to the large molecule limit for spin relaxation. This very desirable property has obviously led to a large number of applications of what is referred to as a transferred NOE or TRNOE. This is one aspect that we will review in some detail below.

While transferred NOEs have been very valuable in providing information on the internal geometry of a bound ligand, they seldom provide information about placement of the ligand on the protein surface. There are some auxiliary experiments that help place ligands. These range from chemical shift perturbation of crosspeaks in HSQC spectra of the protein itself,^{22–24} to perturbation of the intensities of those cross peaks by spin labeled analogs of ligands.^{25–27} In a recent study of human acidic fibroblast growth factor the chemical shift perturbation approach was used to study its interaction with a heparin-derived hexasaccharide.²⁸ Upon titration of the protein with the hexasaccharide, monitored by 2-D ¹H–¹⁵N HSQC spectra recorded after each addition, appreciable chemical shift changes of selected peptide H^N, N, C', and C^α resonances were taken as evidence of a binding interaction. The localization of these perturbations in specific regions implied that the protein underwent no significant overall conformational changes upon formation of the complex. It is worth noting that the magnitude of a given perturbation doesn't necessarily correlate with the strength of the interaction at the associated residue, but it is reasonable to expect that significant chemical shift changes will map residues in or near the contact region with the ligand. Using a similar approach, the carbohydrate binding site of a

family IIb xylan-binding domain was mapped to one face of the protein by titration with a xylohexaose.²⁹

We do not intend to review these applications in further detail, but focus instead on another recent approach that gives both information on internal oligosaccharide geometry and geometry relative to the protein surface. This approach relies on residual dipolar couplings – a parameter that contributes to the splitting of resonances much like a scalar coupling, but one that can only be measured when the molecule of interest is partially oriented in the magnetic field. These parameters again average between free and bound states, and one might expect bound contributions to be too small to be of use in an averaging system. However, the level of order for protein complex and free oligosaccharide need not be the same. If the protein can be induced to order more strongly, properties of the bound form can be detected even in the presence of excess free ligand.

2 TRANSFERRED NOE STUDIES

Transferred NOE studies of oligosaccharides bound to proteins have been reviewed recently.^{30–32} We outline only the basic principles and a few examples here. The structural information obtained from a transferred NOE experiment is in principle the same as that obtained from a normal NOE.^{33,34} Experiments can be conducted in one, two, or three dimensional form. In all cases one will find a segment that begins with a perturbation of the equilibrium magnetization associated with one spin (periodic if multidimensional, inversion or saturation if one dimensional). This is followed by a delay during which magnetization is transferred to nearby spins by dipole-dipole cross relaxation. The spins are nearly always protons because of the high magnetic moment and enhanced efficiency of interaction for these spins. The efficiency of the transfer process depends on the cross relaxation rate, which in turn depends on the inverse of the interproton distance as given by this equation for a pair of interacting protons that tumble isotropically with correlation time, τ_c , in a magnetic field giving a frequency, ω_0 :

$$\sigma_{ij} = \left(\left(\frac{\mu_0}{8\pi^2} \right) h\gamma_i\gamma_j \right)^2 (r^{-6}) \left(\frac{(3\tau_c/5)}{(1 + 4\omega_0^2\tau_c^2)} - \left(\frac{\tau_c}{10} \right) \right) \quad (1)$$

For short delays the transfer is linear with time and the relative intensities (I_{ij} , I_{ik}) of cross peaks (or difference spectrum peaks for a one dimensional spectrum), obey the relation, $I_{ij}/I_{ik} = (r_{ik}/r_{ij})^6$, where r_{ij} and r_{ik} are the distances between a spin pair at an unknown distance and a spin pair at a known distance respectively. For oligosaccharides an intra residue pair of protons such as the H1–H2 pair highlighted in Figure 1 often provide a reference distance, and trans-glycosidic pairs such as H1–H4' are at distances that can provide useful constraints on glycosidic torsional angles.

The transferred NOE differs in that there is an equilibrium between bound and free states. The cross relaxation rates will be different in these states both because of the correlation times for tumbling of the molecules (τ_c) differ and the inter proton distances differ (if the conformation in the bound state differs from that in the free state). If exchange is rapid compared

to cross relaxation the observed effect will be the weighted average:

$$\sigma_{ij}^{\text{eff}} = P_{\text{free}}\sigma_{ij}^{\text{free}} + P_{\text{bound}}\sigma_{ij}^{\text{bound}} \quad (2)$$

Looking at the correlation time dependence of equation (1), it is clear that it is easy to make $\sigma_{ij}^{\text{bound}}$ dominate by binding the ligand to a sufficiently large protein (τ_c increases linearly with molecular weight).

Verifying that one is approximately in this limit is easy. Again looking at equation (1), one sees that the sign of the cross relaxation rate changes as $\omega_0\tau_c$ approaches 1. It is positive for small molecules and leads to intensity enhancement over the equilibrium value; it is negative for large molecules and leads to intensity reductions. Figure 2 shows an example with a simple trisaccharide, methyl 3,6-di-O-(α -D-mannopyranosyl)-(α -D-mannopyranoside), free and bound to mannose binding protein (MBP).³⁵ The anomeric proton resonance from the α (1–3) linked mannose (Man I in Figure 1b) is being inverted. For the free trimannoside, resonances from the nearby intra ring H2 resonance and the H4' resonance of the linked residue are selectively enhanced. For the bound trimannoside, the same resonances, plus a resonance from the H3' trans-glycosidic proton show decreases in intensity.

Quantitative analysis of intensities in terms of distances is actually a little more complex for a transferred NOE. Complexities are illustrated in Figure 3. Rates of exchange

Figure 2 (a) ^1H NMR spectrum of trimannoside (2 mM, 90% D_2O) recorded at 800 MHz. The NOE difference spectrum (298 K) recorded for (b) free trimannoside (2 mM, 100% D_2O , 298 K) and (c) trimannoside bound to Mannose binding protein (0.1 mM, 25 mM Tris-Cl, pH 7.8, 90% D_2O). The NOE difference spectra in (b) and (c) show the result of selective saturation of the H1 anomeric proton of Man I (Figure 1b). In the free state, intra and inter residue positive NOEs are observed for H2 and H4' only. However, in the bound state, the NOEs undergo a change in sign with negative transfer NOEs observed for H2, H3' and H4' protons. The NOE difference spectra were recorded using a saturation transfer scheme, where the H1 anomeric proton was selectively saturated for a long period of time (2 s), followed by a 90° observe pulse to detect the saturation transfer on other protons. A control scan was interleaved in the pulse sequence for the difference spectrum, where the saturation was applied to a region where no resonances are present. The total acquisition time for each difference spectrum was approximately 1 hour and refer to protons from Man III and Man II respectively, while 'Tris' refers to the resonance observed from the Tris-Cl buffer solution in the sample

Figure 3 Effects of spin diffusion on cross-relaxation rates of protons in close vicinity to each other. K_1 and K_{-1} are the exchange rates for protons on and off the protein. The σ 's represent the cross-relaxation rates for individual protons under the influence of other protons in close vicinity

on and off the protein can complicate cross relaxation rates by accentuating spin diffusion effects (three spin effects). Spin diffusion would be a serious concern if the Man II anomeric proton had been inverted and intensity changes in both H6a and H6b resonances of the Man III ring had been seen. The geminal pair, H6a and H6b, are very close (2 Å) and successive transfer from H1 to H6a to H6b is likely to be as efficient as a direct transfer from H1 to H6b. Contributions from the indirect path are normally minimized by shortening the transfer time. But, if the exchange rate is slow, one can reach the point where the time on the protein governs indirect transfer and not the transfer time allowed in the pulse sequence. One solution is to explicitly include exchange and undertake a complete relaxation matrix simulation of transfers.^{36,37} The later presumes that one knows the geometric relationship of all protons that can be involved. This is feasible if they are all on the ligand, but protein protons can also enter as shown in Figure 3. In many cases positions and identities of these protons is not known. Another approach is to collect both transferred NOESY and transferred ROESY experiments.³⁸ ROESY, or the rotating frame analog of the NOESY experiment, has the effect of reducing the effective frequency (ω_0) to the point where cross relaxation is positive for even a large complex. Step wise transfers now give alternate signs for cross peaks, positive for the direct transfer from a saturated or inverted peak, negative for second transfer from the enhanced peak. The difference in sign can identify problem peaks. Quantitatively removing the effects when both direct and indirect pathways contribute can be more of a problem. More recently an approach termed Quite-NOESY has been devised.³⁹ This uses pair wise inversion of peaks in selected spectral regions to eliminate unwanted effects of protein peaks. Because of the distinct regions in which carbohydrate resonances lie in comparison to resonances from protein sidechains, this is often possible in protein-carbohydrate interaction studies.

With the refinements in TRNOE techniques there have been some significant applications to protein-saccharide systems.^{18,40,41} Some of these were reviewed specifically for carbohydrate-protein interactions a few years ago,^{31,42} there are also examples contained in more recent general reviews

of protein-ligand interaction studies.³⁰ One of the more interesting examples is that of oligosaccharide binding to E-selectin or chimeric constructs containing the oligosaccharide binding domain of that protein; this is one of the biologically interesting systems mentioned in our introduction. This system has been the subject of at least five independent studies, many reporting significantly different conformations for the bound sialyl Lewis-X (sLe^x) oligosaccharide (Figure 1) (more than 30 degree deviations in some torsional angles).^{18,43-46} The most recent study used the enhanced resolution of a 3D experiment on ¹³C enriched ligand and complete relaxation matrix analysis of the data in an attempt to resolve the differences.¹⁸ There are significant additional NOEs observed in the heteronuclear experiment that lead to an improved definition of the conformation. Even the most recent study, however, was not able to take account of possible three spin effects from protein protons. The bound ligand, nevertheless, appears to be in a low energy conformation, suggesting that no severe distortions from indirect NOEs exist.

Another recent application to E-selectin takes advantage of transferred NOEs in a different way. This application uses the transferred NOE as a method for screening a library of potential drug lead compounds for those that bind to E-selectin in a selective fashion.⁴⁷ Oligosaccharides and their mimics when near 1000 Da have either small negative or small positive NOEs when alone in solution. As illustrated above for the trimannoside of N-linked oligosaccharides, these turn to strong negative NOEs when bound to a large protein. 2D NOE spectra of a mixture of potential ligands are, therefore, dominated by peaks from compounds that bind to a protein. The authors screened a mixture of 11 compounds that mimic sLe^x. The resulting spectrum was consistent with structural features of only two compounds in the library. Further comparison to NOE spectra for these two led to the identification of the selectively bound compound. While this does not push the structural determination aspects of the transferred NOE the application clearly makes use of one of its unique properties in a way that is of significant use to the pharmaceutical industry.

3 RESIDUAL DIPOLAR COUPLING STUDIES

The same dipolar interaction that gives rise to the NOE actually contains both angle and distance dependent terms. This can be seen in equation (3) written for the interaction in frequency units for a pair of spin 1/2 nuclei (i, j) separated by distance r along a vector at angle θ relative to the magnetic field. Both terms are in principle useful sources of structural information.

$$D_{ij}^{\text{res}} = - \left(\frac{\mu_0}{4\pi} \right) \frac{\gamma_i \gamma_j \hbar}{2\pi^2 r_{ij}^3} \frac{(3 \cos^2 \theta - 1)}{2} \quad (3)$$

In the NOE, the angle dependent part is responsible for modulation of the interaction as a protein tumbles in solution and is essential for making the distance dependence of NOEs measurable as a spin relaxation phenomenon. However, it normally makes no direct contribution to spin state energy differences that might be efficiently measured through variations in resonance positions. This is because the angular term

rigorously averages to zero over the time course of molecular tumbling in isotropic solutions.

If the angular term did not average to zero, the interaction between a pair of distinguishable spin 1/2 nuclei would lead to a splitting of each resonance of magnitude D_{ij}^{res} . This would appear much like a scalar coupling, and in fact, the contribution would simply add to the scalar contribution to splitting when both contributions were present. In the case of directly bonded pairs of spin 1/2 nuclei (^1H – ^{15}N , ^1H – ^{13}C , etc.), where the internuclear distances are known, the residual dipolar contribution to splitting would become a simple function of internuclear vector orientation and a rich source of structural data.

Direct measurement of residual dipolar couplings from resonance splittings, thus, depends on restoring some level of directional order to molecules as they tumble in solution. To maintain high resolution we would want the level of order to be small because large levels would produce large residual interactions and strong coupling among spins much as we see in solids NMR. Restoring small levels of order has a lot of precedence in the liquid crystal field⁴⁸ and in work with paramagnetic molecules that simply orient in the presence of high magnetic fields.⁴⁹ Recently there has been a revival of interest in working with partially ordered molecules of biological interest using aqueous liquid crystal media including bicelles,^{50–52} phage,^{53,54} cellulose microcrystals,⁵⁵ cetylpyridinium chloride/hexanol/brine,⁵⁶ and mechanically distorted polyacrylamide gels.^{57,58}

Inducing small levels of order, as opposed to perfect order, adds a complication in that the level and anisotropy of order for the whole molecule become variables in addition to the orientation of an interaction vector of interest. These additional

variables are conveniently included in equation (3) as follows:

$$D_{ij}^{\text{res}} = - \left(\frac{\mu_0}{4\pi} \right) \frac{\gamma_i \gamma_j \hbar}{2\pi^2 r_{ij}^3} \sum_{kl} S_{kl} \cos(\alpha_k) \cos(\alpha_l) \quad (4)$$

Here the angular term has been expressed in terms of elements of an order tensor (S_{ij}), and direction cosines relating the internuclear vector to a principal order frame ($\cos(\alpha_k)$).⁵⁹ Despite the apparent complexity of the equation, it has only five independent parameters; these can alternately be described in terms of three Euler angles relating the orientation of a molecular fragment to a principle alignment frame and principal and rhombic alignment parameters.⁵² If a sufficient number of independent measurements of dipolar couplings can be made within a semi-rigid fragment, the five parameters can be calculated directly and complete structures assembled from orientations of fragments relative to a common alignment frame. When fewer data are available the measurements can be used as constraints in more general structure search protocols.

Part of the appeal of residual dipolar couplings measurements is the efficiency with which these data can be acquired. Measurement of ^{13}C – ^1H dipolar couplings of directly bonded pairs in a sugar ring can be based on simple modifications of an HSQC experiment. Modifications can be as simple as removing the normal 180° pulse used for refocusing proton scalar coupling during the indirect detection period. When this is done, the single cross peak for each pair turns into a doublet with a splitting at the sum of one bond scalar and dipolar contributions. The resulting spectrum is illustrated in Figure 4 for the trimannoside core found in all N-linked glycosides. These data were taken at natural abundance on a 20 mM sample with approximately a 6 hour acquisition. With new cryogenic probes

promising to increase sensitivity of NMR spectrometers by a factor of three or four, work with 2–3 mM samples should be feasible in 24 hour acquisitions. The dipolar part is usually extracted by acquiring spectra under both isotropic and oriented conditions. This can be simply done using bicelle systems in which isotropic and ordered states can be produced by changing from lower temperature to higher temperature (e.g., from 25 to 35 °C). At 25° only scalar couplings contribute, and splittings are all of similar magnitude. At 35° the bicelles, which are simply discoidal pieces of lipid bilayer, order with normals perpendicular to the magnetic field. Occasional collisions of the oligosaccharide with the ordered surfaces impart a small degree of order; the dipolar contributions to couplings between ^1H and ^{13}C nuclei fail to average to zero, and splittings increase or decrease depending on the angles that a particular internuclear vector makes with the axes of the order frame. There are of course a number of more sophisticated pulse sequences that allow measurement of ^1H – ^{13}C couplings from either intensity variation or frequency variation of cross peaks.^{51,60,61} Also, experiments that allow measurement of ^1H – ^1H interactions have been devised.^{56,62} The use of several different kinds of coupling allows sufficient interaction vectors to be measured within single sugar rings.

The Z axis is perpendicular to the O-C1-C2 plane and the Y axis is along O-C1 bond.

$$X = \lambda \cos \phi, Y = \phi$$

where ϕ is the latitude and λ is the longitude

Figure 5 Illustration of structure determination for a simple oligosaccharide using the order tensor approach. The direction of highest order is represented by a director in the initial molecular frame denoted by X, Y and Z axes (derived from Ref.⁶⁸)

Figure 6 Sauson-Flamsteed projections of two rings of trimannoside depicting the orientations of the alignment tensor principal axis system in the initial molecular frame (derived from Ref.⁶⁸)

One structure determination approach is illustrated in Figure 5 for a simple oligosaccharide. Pyranose rings are considered to be semi-rigid fragments and a canonical fragment frame is defined using the C1, O5, and C2 atoms. Measured couplings are used to define both order parameters and directions of alignment frame axes relative to the fragment frame. These axis directions are often depicted as points on a globe called a Sauson-Flamsteed projection as shown for the z axis in Figure 5. Normally x and y axis directions are depicted as well. Figure 6 shows the projections for two rings of the trimannoside core of common N-linked glycosides discussed previously. Note that axis directions come in pairs offset by 180 degrees. This insensitivity to inversion is a fundamental limitation of the measurements and normally leads to a four fold degeneracy in choice of fragment orientation. For sugar residues directly connected by short glycosidic bonds covalent geometry restrictions often lift this degeneracy as well as fixing translational degrees of freedom. The use of multiple alignment media can also lift this degeneracy. Figure 7 shows the derived structure.

Incidentally, the third ring of the trimannoside cannot be aligned so easily. Its principal order parameters depart significantly from those of the other two, a clear indication that internal motions exist and that the entire molecule cannot be considered a single rigid structure. There are now several other examples of structure determination of oligosaccharides using primarily residual dipolar coupling data.^{56,63} Some of these studies have also highlighted the detection and characterization of internal motions in oligosaccharides.⁶⁴

Using residual dipolar coupling to deduce the geometry of protein bound oligosaccharides is still in its infancy. As

Figure 7 (a) The average structure of trimannoside ring I and ring III assembled by aligning the order tensor principal axis determined from bicelle media. Superimposed on ring I and ring III are coordinate frames representing the order tensor principal axis determined separately for each ring. (b) The average structure of trimannoside ring I and ring III assembled by aligning the order tensor principal axis determined from phage media. The structure is oriented to show the similarity of conformations about the α (1,3) linkage

suggested above the key to the widespread use of these measurements would be an alignment medium that strongly oriented the protein and weakly oriented the free oligosaccharide. Such an ideal medium has not yet been found, but even moderate preference for protein alignment combined with known binding constants have allowed deconvolution of residual dipolar couplings coming from the bound state. The necessity of working with higher protein to ligand ratios than required in transfer NOE experiments has restricted measurements to ^{13}C enriched oligosaccharides and measurements of one bond ^{13}C – ^1H couplings. Nevertheless some interesting examples have appeared. In one the binding of the trisaccharide, $\text{Gal}\alpha 1\text{-4Gal}\beta 1\text{-4Glc}$ to the B subunit of an *E. coli* toxin was examined. The relative orientation of the two Gal residues could be determined and was found to agree with a conformation determined via transferred NOE methods.⁶⁵ Significantly, the authors point out that the data are free from protein mediated effects in transferred NOE experiments and can be made with significantly lower amounts of material. In a second application to the same trisaccharide, which happens to constitute the oligosaccharide from the glycolipid receptor of verotoxin-1 B subunit, data were used to distinguish among conformations found for different sites occupied in the crystal structure of the oligosaccharide verotoxin complex.⁶⁶ The derived data fit the conformation seen in site two. In this case transferred NOE data had been inadequate to distinguish between two previously proposed oligosaccharide conformations for this site.

In a third application the binding of a simple methyl glycoside, α -methyl mannose, to mannose binding protein was studied.⁶⁷ This study was different in that the target was determination of relative orientation of protein and a single sugar ring rather than relative orientations of multiple rings. In general one would have to use a structure for the protein and ^{15}N – ^1H dipolar coupling from the protein to derive the orientation of the protein. In the case studied this step could be eliminated because of the existence of a three fold rotational symmetry axis in the trimeric protein. The placement of the ligand in the binding site was found to be energetically allowed, but significantly different from that observed in a crystal structure of a homologous complex.

Although preliminary in nature and small in number, these examples of applications to protein-oligosaccharide complexes are promising. The advantages in not having to observe large numbers of inter-residue NOEs to constrain conformation, and the avoidance of complications due to spin diffusion are very significant. Improvements in sensitivity coming from cryogenic probes should allow increased use of molecules at natural abundance, and improvements in media allowing amplification of bound oligosaccharide data should allow greater use of ^1H – ^1H couplings in the future.

Biographical Sketches

James Prestegard received his B.S. in chemistry in 1966 from the University of Minnesota and his Ph.D. in chemistry from the California Institute of Technology in 1971. Prior to joining the CCRC in January 1998, Dr. Prestegard spent 27 years in the Chemistry Department at Yale University where he held positions of assistant professor, associate professor, and professor. In addition to his normal professorial duties, he now directs the regional NMR facilities at the University of Georgia. Dr. Prestegard serves on the editorial boards of several journals, including the *Journal of Magnetic Resonance* and the *Journal of Biomolecular NMR*, and is a frequent member of advisory and review panels.

Nitin U. Jain, b 1973. M.S., 1995, Ph.D., 1999, Brandeis. First involved with NMR on joining Brandeis University in 1995, where he worked on the NMR of paramagnetic proteins and was involved in developing strategies for the assignment of heteronuclear resonances in the paramagnetic region of ferredoxins in particular. Approx. 6 papers and 1 patent in NMR related aspects. Research interests: NMR studies of protein-carbohydrate interactions using residual dipolar couplings.

Steven B. Levery received his B.A. (1971) and M.S. (1975) in chemistry from Northeastern University, and his Ph.D. (1993) in chemistry from the University of Washington. He spent 15 years in the laboratories of Dr. Sen-itiroh Hakomori, initially as a research technologist and supervisor in glycoconjugate structural analysis at the Fred Hutchinson Cancer Research Center, Seattle, WA (1980–1987); and later as a staff scientist and head of the laboratory for Analytical & Structural Biochemistry at the Biomembrane Institute, Seattle, WA (1987–1995). He is currently an Associate Research Scientist in the University of Georgia Complex Carbohydrate Research Center (CCRC) and Department of Biochemistry and Molecular Biology; he is also Technical Director of the NIH Resource for Biomedical Complex Carbohydrates located at the CCRC.

1 INTRODUCTION

Signals induced by a variety of polypeptide growth hormones are transduced from cell surface receptors through pathways of interacting cytoplasmic proteins. Many of these intracellular signal transducing proteins, notably the non-receptor protein kinases, contain Src homology 2 (SH2) regions,¹ which have a strong binding affinity for target protein sequences that contain a phosphorylated tyrosine residue. Many receptors have tyrosine kinase domains that are directly activated by ligand binding and which autophosphorylate themselves, creating binding sites for proteins with SH2 regions.

The *c-abl* gene product is a nonreceptor tyrosine kinase that, when mutagenically activated in a variety of ways, can induce neoplastic transformation of pre-B cells and fibroblasts. An intact SH2 region is required for the transformation by activated c-Abl. The oncogenic activity of the Abl oncoprotein appears to depend on the ability of the SH2 to bind phosphotyrosine, since a series of conservative point mutations in the highly-conserved FLVRESSES motif of the SH2 region coordinately impaired both binding to tyrosine-phosphorylated proteins and transforming activity.² It was suggested from these studies that the Arg and two Ser residues of the FLVRESSES motif were involved in phosphotyrosine binding.

2 SOLUTION STRUCTURE OF THE Abl SH2 DOMAIN

The solution structure of the SH2 of Abl has been determined and consists of a compact α/β domain with a phosphotyrosine ligand-binding site on a face distal from the termini. Assignments of nearly all ¹H and ¹⁵N resonances of the SH2 domain have been obtained from homonuclear and heteronuclear NMR experiments.³ The tertiary structure has been calculated using 1754 interproton distance constraints, 33 pairs of hydrogen bond constraints and 79 pairs of ϕ angle

constraints and is well defined with regular secondary structure the two β -sheets and two α -helices.⁴

A family of solution structures determined from NMR constraints reveals that the SH2 domain of Abl contains two antiparallel β -sheets and two α -helices folded together in an apparently novel fashion (Figure 1).⁴ The arrangement of secondary structural elements ('supersecondary structure') determined by NMR³ was used to trace the backbone elements through the electron density of the Src SH2, leading to a high-resolution crystal structure for two low-affinity peptide complexes.⁵

Protein structure determination by NMR provides information about secondary structural elements at an early stage, so this cooperation with X-ray structure determination may be expected to be repeated. Comparison of NMR and X-ray determined structures is obviously of significance in identifying crystal packing effects, and variations of structure associated with solution conditions. Additionally, early levels of structural detail from NMR provide the information needed for a structural biological analysis—the general topology of the protein, surface features likely to provide binding sites, improved alignment of the family of sequences related to the target sequence, modularity of the structure, and explanation of previous mutagenesis experiments.

3 GENERAL TOPOLOGY

The central architectural feature of Abl SH2 is a large antiparallel β -sheet that consists of the three strands; β B(32–38), β C(44–51), and β D(54–60) (Figures 1 and 2). Based on mutagenesis data discussed later, it appears that the putative phosphotyrosyl binding site is formed by conserved residues in this sheet and in a short amphipathic α -helix, α A(17–25), that runs along the central strand. Arg-18 emerges from underneath the helix to lie over the aromatic ring of His-57 on β D (see Figure 1). Arg-36, an absolutely conserved residue in the FLVR sequence, projects toward Arg-18 from β B. A conserved positively charged residue represented by Arg-59 in the Abl SH2 domain is located on β D across from Arg-36. All three arginine side chains are solvent exposed and structurally unconstrained at their termini. Crystallographic studies definitively establish this area as the site of phosphotyrosine binding in phosphotyrosyl peptides.^{5–7}

4 STRUCTURAL AND SEQUENTIAL ALIGNMENT OF RELATED SEQUENCES

A group of SH2 domains³ are aligned with the Abl sequence on the basis of conserved secondary structure in Figure 2. Particular emphasis has been placed on the preservation of glycine and proline residues at turns and to the retention of the amphiphilic character of β -strands and α helices. Deletions and insertions are placed in loop-and-turn regions. Considerable conservation of amino acid identity or at least hydrophobicity allow all the elements of secondary structure including the six β -strands, two mini- β -strands, and two α helices to be aligned relatively easily by visual inspection. The hydrophobic face of the α A-helix spanning Ser-17–Leu-25 in Abl contains conserved leucine and alanine residues. Likewise,

Figure 1 Schematic ribbon drawing of the Abl SH2 domain. Strands are shown in light green (β B, C, D, D', E, F). Helices are colored red. The N- and C-termini are indicated. Three arginyl residues implicated in the binding site are shown as full side chains; the positions of atoms beyond the β atoms is arbitrary. These are Arg-36 (light green), in the FLVR sequence (see text), Arg-18 at the end of the first helix (yellow), and Arg-59 (light blue). The side chain of His-57, close to Arg-18, is also shown in dark blue

the hydrophobic face of α B consisting of residues Leu-79, Leu-82, Val-83, His-83, and His-86 in Abl is conserved.

The length of the α A– β B loop is highly conserved. An exception is the N-terminal SH2 of PLC- γ 1 where a five-residue insertion including two glycines and two oppositely charged residues is inserted to form a flexible and exposed loop. Also highly conserved is an aliphatic residue in the third position of the loop. This hydrophobic residue is represented by Val-15 in the Abl SH2 and is in a position to interdigitate with the conserved leucine of the FLVR sequence. Such an interdigitation could not be confirmed with NOEs due to the lack of a complete Leu-34 spin system assignment. However, only the C-terminal p85 α SH2 does not have an aliphatic at this position in β B. In addition, the C-terminal p85 α SH2 is the only SH2 without an aromatic residue immediately following the absolutely conserved tryptophan. This pattern suggests a structural interaction between these two spatially proximal residue positions (on β B and the mini- β -strand, β A) that can take the form of either a polar–polar (as in p85 α) or aromatic–aliphatic stabilizing interaction.

The large β -sheet is the most highly conserved region. No glycines are found in any of the SH2 sequences here, indicating that the curvature of the sheet is maintained. However, a proline is found in the sixth position of β B in the SH2 of

D-Src1 and the N-terminal SH2 of PTP1C. This proline would alter the inflection of the phosphate binding loop.

Two classes of junction between β C and β D are evident in Figure 2. Most SH2 domains are similar to the Abl sequence with a tight turn formed at Glu-52–Gly-53. The sequence alignment with other SH2 sequences shown in Figure 2 reveals that although the consensus sequence for such a type II turn is Xxx–Gly–(Ser/Thr)–Xxx, in SH2 domains the second position of this turn is usually occupied by a charged or polar residue while the third position of this four residue turn is typically a glycine. In contrast, SH2 domains from the *src* family have a hydrophilic insertion here while maintaining a Gly at the last turn position. Such an insertion does not disrupt the pairing of conserved residues, it merely extends the loop. The larger size of this turn in Src suggests the name ‘Src family insertion point’. Those SH2s that contain such an insertion invariably include an aromatic at the first position of the turn and invariably have a simultaneously inserted leucine immediately following α A. As these positions on the two loops are near each other, a stabilizing hydrophobic interaction could occur between them.

The point of juncture between the two β -sheets is conserved except in the cases of Crk and the N-terminal SH2 domains of PLC- γ 1 and PLC- γ 2. Due to the amino acid sequence heterogeneity in the β D' strand, it is difficult to predict whether the insertions in these three SH2s would contribute to D/E or E–F loops. In the case of the Crk SH2, the insertion consists of 17 residues consisting primarily of alanines, arginines, glycines, and prolines. The glycine in the D/E loop is highly conserved and suggests the conservation of a β -bulge here.

The conservation of the final turn of the α B-helix is relatively poor. For example, positively charged dipeptides could serve to disrupt the third turn of this helix in the C-terminal GAP, Hck, Nck, and PTP-1C SH2 domains, and may impact the shape of the hydrophobic pocket found to provide specific interactions with bound peptides in the crystal structures of Src and Lck SH2s. An extended sequence with considerable heterogeneity in both length and amino acid composition follows α B. In the cases of SH2 domains of the p85 α , Nck, Vav, Fps/Fer, and PTP1C types, sufficient sequence is inserted to allow the formation of a two stranded antiparallel β -sheet as has been found in the case of the N-terminal p85 α SH2.⁸

5 COMPARISON WITH OTHER DETERMINED SH2 DOMAIN STRUCTURES

Two other SH2 domain structures were reported at the same time as the Abl SH2 domain structure. The crystal structure of the Src SH2⁵ and the solution structure of the N-terminal p85 PI 3-K⁸ do not differ in their folds from each other or the Abl SH2 structure. Two minor differences result from small insertions. Five additional residues are found between the β B and β C-strands in the Src SH2 and result in the formation of a hydrophobic loop which is disordered in the crystal structure. Insertion of several residues after the helix α B of the p85 α SH2 introduces a second strand which pairs with a second strand similar to the extended segment that runs through the core of the Abl SH2.

A difference between the number of β -strands in the solution and crystal structures was originally reported as being

Figure 2 Alignment of SH2 sequences with that of Abl based on the derived secondary structure of Abl. Most sequences were previously tabulated.¹ Amino acid residues are numbered relative to the c-Abl SH2 sequence. The naming of the segments follows previous suggestions⁶

due to the addition of two mini- β -strands which pair with the β B-strand of the crystal structure. The NOE spectra of the Abl SH2 have been reinvestigated to determine if two such mini- β -strands are present and if they align with the β B-strand in a parallel fashion. A conserved parallel alignment is found for the two mini- β -strands. However, the weak $d_{\alpha\alpha}(12, 36)$ NOE and $d_{\alpha\alpha}(32, 99)$ NOEs indicate that the two mini- β -strands do not have standard pairing interactions with β B. The majority of stabilizing interaction juxtaposing the elements originate from buried aromatic groups rather than conventional interstrand forces such as hydrogen bonds.

Structural comparisons to the peptide-bound form of the Src SH2⁵ reveal differences in the conformation of the phosphate binding loop. In the case of the Src SH2, this loop is more inflected and is hydrogen bonded to the bound phosphate, while in the Abl SH2 this loop is more disordered and less inflected. The relative orientation of the helices and sheets are essentially identical.

There is, however, ample evidence that there are significant variations in some SH2 structures in other gene products. For example, the SH2 in STAT91 is likely to be significantly different in the C-terminal portion of its structure from the SH2s mentioned here, on the basis of alignment, and its probable role in forming a dimer on phosphorylation in a intermolecular self-recognition complex.⁹

6 LIGAND BINDING FOR Abl SH2

Previous mutational studies have established the significance of the 'FLVRESES' site for phosphotyrosine binding.² The disruption of binding by conservative mutations of the Arg-36, Ser-38, and Ser-40 residues in this motif can be seen to be consistent with their exposed positions on the β I-strand and phosphate binding loop. In the Abl SH2 domain structure, the side chains of all three residues are exposed with the serine residues projecting from the side of the five-residue β B- β C loop that is inflected toward Arg-36. Other studies have found that mutation of the conserved Arg-18 and His-57 residues perturb the function of SH2 domains.¹⁰⁻¹² In the Abl SH2 domain structure, the aromatic ring of His-57 contacts the side chain of Arg-18 while the side chain of Arg-36 is nestled between α A and β C, and in some structures is oriented towards the His-57 ring. The spatially proximal side chain of Arg-59 is also in a position to contribute to the binding of the phosphotyrosine. The buffer specific chemical shifts of the amide resonances of Glu-39 and Ser-41 in the phosphate binding loop described earlier also provide experimental evidence for the role of the loop in phosphate coordination.¹³ The specific interactions of this phosphotyrosine ligand binding mechanism can be seen in the peptide-Src SH2 complex crystal structure.⁵ The high degree of conservation of Arg-18, Arg-36, and His-57, and the preference for a positive charge at residue 59, suggest that this basic cluster constitutes a common phosphotyrosine binding site within the SH2 domain family.

The two loops tethering α A to the rest of the domain appear to be flexible, with conserved glycyl residues found at either end. Within the SH2 domain family the exposed residues of the central β C-strand maintain a preference for small polar residues, providing a 'slick' surface that could allow α A to shift transiently from its alignment along β C. A

helix-containing 'trough' on the surface of the major β -sheet is formed by Val-55 on β D and Leu-34 on β B. The exposed side chains of Ala-20 and Leu-24 on the helix could then roll from their exposed positions toward conserved Leu-34 on β B during the insertion of a phosphotyrosine group. Furthermore, the lack of slowly exchanging amides in all but the last residue of the α A-helix suggests that the beginning of the helix which points into the binding site is conformationally flexible.

The crystal structures of Src⁷ and Lck⁶ complexed with specifically bound peptides containing the pYEEI (pY = phosphotyrosyl residue) sequence reveal a number of intermolecular polar and hydrophobic interactions. These interactions presumably determine the peptide specificities of the Src class of SH2s. The Abl SH2 binds with highest affinity to pYENP sequences,¹⁴ implying that contacts to the pY + 2 and + 3 positions should provide discrimination between the specificity of the Abl and Src-type SH2s. No direct contacts are made to the pY + 2 Glu in either SH2 crystal structure, although two water-mediated hydrogen bonds are made to Ile and Arg of Src SH2 that are equivalent to Val-70 and Asn-61, respectively, in the Abl SH2. The Arg-Asn-61 substitution in the SH2s may result in the Glu-Asn specificity switch at the pY + 2 positions. Thus, electrostatic interactions appear to constitute a specific determinant for the pY + 2 position of the peptide.

A hydrophobic pocket engulfs the pY + 3 position of the Src SH2 and Lck specific complexes. This hydrophobic pocket is formed from the β E- β F loop and the loop following α B. Of the Src and Lck SH2 residues that contact the pY + 3 position, only three differ in the Abl SH2 but do not differ between Lck and Src. Equivalent positions in the Abl SH2 sequence to these residues are Val-70, Glu-73, and His-86, and correspond to an Ile, Arg, and Tyr, respectively, in the Src/Lck sequences. The interaction provided by the C γ H₃ group of the Ile could be mimicked by Abl's Val-70. The Arg side chain lies over the rim of Lck's hydrophobic pocket to contact the pY + 4 backbone carbonyl group. In the Abl SH2, the Glu at this position could fold over the pocket but would not be expected to interact in an analogous electrostatic manner with the residue at position pY + 4.

The last residue capable of directly determining peptidic specificity is the buried aromatic provided by α B. This residue is highly conserved and is represented by a Tyr and a His in the SH2s of all members of the Src and Abl families, respectively. In the case of the Src SH2, the *meta* position of the Tyr is 4.4 Å from the C δ H₃ of the peptide's Ile at position pY + 3. Abl SH2's His-86 would not make a comparable contact to a Pro at this peptidic position since the Pro would not be expected to insert as deeply into the core. However, subtle differences in the core architecture could allow the Abl SH2 domain to make specific interactions to the pY + 3 proline.

7 MODULARITY OF THE SH2 DOMAIN

The residues between Trp-11 and Leu-97 appear to be absolutely necessary to form the tightly packed structure of the Abl SH2 domain. Both residues contribute to the hydrophobic core and are absolutely conserved. The tryptophan side chain is very bulky, and it acts as an essential anchor by holding the first mini- β -strand against the β B-strand. Similarly, the bulky leucine side chain acts to anchor the sequence immediately

prior to the second mini- β strand (G) in the hydrophobic core. Turns near both the C- and N-terminal regions direct the two termini in a parallel fashion away from the body of the domain. This orientation would allow the SH2 domain to be rooted by its termini on the surface of a larger protein while leaving its putative ligand-binding region exposed to solvent.

8 MUTAGENIC DATA EXPLAINED BY THE STRUCTURE

A large number of mutations of SH2 domains have been generated by several groups to explain SH2 behavior. The effects of these mutations can now be reinterpreted in the light of the conserved tertiary structure. In particular, mutations that appear to disrupt the binding of the phosphotyrosine or the adjacent ligand sequence and would disrupt the tertiary structure were generated. For example, the apparent destabilization caused by mutation of the Phe of c-Src's FLVR sequence to a Pro¹⁵ can be seen to result from the major perturbation it would cause in the twist of the major β -sheet.

A number of mutations of the c-Src SH2 result in increased kinase and/or transforming activity but are not as transforming as v-Src,¹² presumably by disrupting the intramolecular autoinhibitory association between the Src's C-terminal, phosphorylated Tyr-527 residue with its adjacent SH2 domain. In particular, point mutations of the absolutely conserved, N-terminal Trp to an Arg, of the conserved Arg in α A involved in ligand recognition to a Ser, or of the Gly immediately preceding β B to a Leu in c-Src all appear to deactivate the SH2. The Arg-Ser mutant would remove a point of coordination of the bound phosphotyrosine and would lead to a direct loss of SH2 binding function. The Trp-Arg mutation would introduce a buried charge and would be destabilizing. The Gly-Leu mutation introduces an exposed aliphatic that could be destabilizing or complicate the folding of the domain, or else it could deactivate the SH2 by lowering an essential conformational flexibility of the attached α A-helix.

Mutation of the Ser at the fifth position of the β C strand to a Glu slightly reduced kinase and transforming activity of Src,¹⁶ presumably by altering the packing of the α A-helix against the β -sheet and thus compromising the phosphotyrosine binding interactions. Replacement of the Glu at the fifth position of the α A-helix to an Ala, Asp, or Lys residue all reduce the kinase and catalytic activity of Fps in a similar fashion.¹ Substitution of the conserved and exposed Tyr in the N-terminal mini- β -strand with a Ser-Arg-Asp tripeptide dramatically reduced the transforming activity of Fps,¹⁷ presumably by deactivating the SH2 by altering the structure of the phosphate binding site. Also not surprising is the negligible effect¹⁶ of replacing the exposed second Arg of the α A of Src SH2 with a Leu since this Arg plays no identified role in phosphopeptide recognition.

A few mutants relevant to peptide binding specificity determinants have also been reported. Most significantly, the Arg-205 $\rightarrow$ Leu mutation would be predicted to change Src's specificity for the pY + 2 peptide position, since this residue makes specific contacts to the peptide in the SH2-peptide complex.⁷ In fact, no change in the transforming or kinase activity of this Y527F-derived Src mutant was found,¹⁶ indicating that the specificity of the SH2s was not discernibly

affected. Mutation of the conserved Val in the buried portion of central turn of α B to a Glu would be expected to disrupt core packing and the hydrophobic pocket that contacts the pY + 3 position of the peptide.⁷ A small gain of function of this Y527F Src mutant, however, was reported¹⁶ indicating that the transforming role of Src can be independent of the ability of its SH2 to bind peptide specifically.

9 CONCLUSIONS

The modular design of the SH2 domain allows it to be easily inserted into protein sequences without gross structural changes and permits the formation of multidomain assemblages with interactive signalling functions. The novel fold of this structure was elucidated independently for Abl and the simultaneously reported and topologically identical SH2 domains of the p85 α ⁸ and Src⁵ proteins. The Src SH2 crystal structures were determined using the secondary and supersecondary structure information from the Abl SH2 to trace several disordered loops connecting the resolved β -strands and α -helices, and to determine β strand directions. Those crystal structures provided a defined view of the ligation of phosphotyrosine and how this is discriminated from other phosphorylated products. This is the first reported use of supersecondary NMR information to trace a crystal structure of a protein with a novel fold, and demonstrates the emerging power of NMR as a structural biology tool. NMR structural information at many levels provides a rich source of interpretation of the results from complementary biological techniques.

1 INTRODUCTION

Current understanding of the structure and dynamics of lipids in membranes is, to a large extent, promoted by the availability of various membrane model systems. Sonicated membrane vesicles, or small unilamellar vesicles first characterized and prepared by Huang in 1969, have been utilized extensively in NMR studies because of the high-resolution features in their spectra. A reflection on how the original idea was conceived to prepare a homogeneous fraction of a sonicated membrane vesicle is given by C. Huang.¹ Much structural and dynamic information of membrane lipids was thus inferred before the advent of solid state NMR spectroscopy suitable for unsonicated membrane studies. Therefore, solution NMR studies of sonicated membrane vesicles may be considered to have played a pioneering role for the solid state NMR investigation of planar membranes.

The interest in studying sonicated membrane vesicles, however, extends beyond a simple model membrane system for NMR studies. There is a growing interest in how curvature of the lipid/water interface affects packing of the lipid acyl chains.^{2,3} It has been suggested that the curved membrane surface may be important in affecting protein–lipid interactions. The discussions and endeavors for settling the controversial issue in the interpretation of fatty acyl chain order derived from NMR studies of small vesicles in comparison to planar membranes has also attracted many ingenious NMR approaches. Progress in the application of NMR lineshape analysis to studies of the molecular ordering and conformations of membrane lipids and in the interpretation of nuclear spin relaxation experiments has been made possible partially because of these efforts.

One of the important criteria for the quantitative interpretation of the NMR spectra of sonicated membrane vesicles, unfortunately often neglected, is the homogeneity of the spin systems used for experiments.

First, simple sonication of aqueous dispersions of phospholipids does not produce the homogeneous preparation of vesicles. In fact, the vesicles produced by extensive ultrasonication are extremely heterogeneous if they are not further purified carefully by gel filtration or ultracentrifugation. From the

practical standpoint of model membrane preparation, gel filtration chromatography is highly suitable for the fractionation of phospholipid vesicles after phospholipids have been subjected to prolonged ultrasonic irradiation in buffered aqueous solution under an N₂ atmosphere. Although ultracentrifugation can, in some cases, yield a similar homogeneous preparation, it should be borne in mind that the centrifugation conditions for vesicles with different lipid composition are different, and thus subject to variation depending on the preparation. (Many drawbacks of the gel filtration technique listed by Barenholz et al.⁴ can be avoided by using the new gel filtration medium.)

Secondly, severe surface curvature in small unilamellar vesicles imposes structural and dynamic differences on the lipid measurements of the inner and outer monolayers of small vesicles; the two halves of the bilayer have different radii of curvature both in sign and magnitude. Therefore, even if a homogeneous vesicle system is used, the obtained NMR signals, if not distinguished between the inner and outer monolayers, would still contain intrinsic heterogeneous factors. In this respect, the ¹H NMR spectra observed at low frequency or the ²H NMR spectra obtained from synthetic lipids should be considered as superimpositions of two spin systems in sonicated membrane vesicles.

In order to illustrate how NMR studies can lead to useful information about the molecular order and packing arrangement of phospholipid in vesicles, we first consider sonicated phosphatidylcholine vesicles. The single-component phosphatidylcholine vesicle system has been well characterized by many physical techniques, including ¹H NMR, ²H NMR, ¹³C NMR, ¹⁹F NMR and ³¹P NMR. The results of these studies not only provide information concerning the monolayer packing asymmetry of phosphatidylcholine in highly curved vesicles (Section 2), but also shed light on the membrane structure and dynamics (Section 3). Finally, we consider how the NMR studies of other lipid vesicle systems could add an additional dimension in future membrane studies (Section 4).

2 MONOLAYER PACKING ASYMMETRY IN BILAYERS WITH CURVATURE

Sonicated membrane vesicles have been widely used as a model system for magnetic studies, not only because of the suitability of their homogeneous preparations for solution NMR investigations, but also due to the availability of a large number of physical properties. Herein, we illustrate how these physical properties, with the help of the information provided by NMR measurement, could lead to additional understanding of the membrane bilayer structure at molecular level.

2.1 Combined Hydrodynamic and NMR Measurements

From a series of hydrodynamic studies,⁵ sonicated egg phosphatidylcholine vesicles were shown to be spherical with unhydrated vesicle radius (R_c) of 99 Å and molecular weight (M) of 1.88×10^6 Da. Since the partial specific volume (v), or the average volume per lipid molecule, has been determined to be 0.9848 mL g⁻¹, one can thus impose a simple geometric constraint on the vesicles as follows:

$$M = \{768 \text{ Da}(n_o + n_i)\} = N(\frac{3}{4}\pi(R_c^3 - R_a^3))/v \quad (1)$$

where 768 Da is the average molecular mass of an egg phosphatidylcholine molecule, N is Avogadro's number, R_a is the radius of the water cavity trapped inside the vesicle, and $(n_o + n_i)$ is the summation of the number of molecules in the outer monolayer, n_o , and in the inner monolayer, n_i , of the spherical vesicle. Assuming that the average volume per lipid molecule is the same for the phosphatidylcholine molecules in the two monolayers of the vesicle, i.e., $v_o = v_i$, one can obtain the other geometric constraints as

$$n_o/n_i = (R_c^3 - R_b^3)/(R_b^3 - R_a^3) \quad (2)$$

$$v_o = \frac{4}{3}\pi(R_c^3 - R_b^3)/n_o \quad (3)$$

$$v_i = \frac{4}{3}\pi(R_b^3 - R_a^3)/n_i \quad (4)$$

where v_o and v_i are the volume available to each lipid molecule within the outer monolayer and the inner monolayer, respectively, and R_b is the radius at the acyl chain interface between the two lipid monolayers. One can therefore solve all the geometric radial parameters (Figure 1) if the value of n_o/n_i , the ratio of the number of molecules in the outer monolayer to that in the inner monolayer, can be measured.

Paramagnetic ions such as europium (Eu^{3+}), when applied exogenously to the sonicated membrane vesicles, shift the NMR signals of the accessible lipid molecules.⁶ Since the membrane bilayer is impermeable to most ions and the osmotic effect of small vesicles is negligible, the amount of lipid molecules located either in the inner or the outer monolayer can be determined by simply measuring their respective NMR signal intensity. After considering the change of the signal intensity caused by the relaxation effect of the shift reagent introduced, the molecular ratio of the two halves of sonicated egg phosphatidylcholine vesicle bilayers has been spectrally determined to be about 2.1. Similar results can also be obtained by employing various lanthanide ions in ^1H , ^{13}C , and ^{31}P NMR

studies to determine the phospholipid asymmetry in vesicle bilayers.⁵

The packing parameters for the sonicated egg phosphatidylcholine vesicles have been calculated on the basis of NMR values of n_o/n_i and equations (1) and (2). The results are illustrated in Figure 1. It can be seen that the average area per molecule for lipids in the *outer monolayer* is less at the center ($46 \text{ \AA}^2$) of the bilayer than it is at the surface ($74 \text{ \AA}^2$), whereas for lipids in the *inner monolayer* the average area per molecule is greater at the bilayer center ($97 \text{ \AA}^2$) than at the surface ($61 \text{ \AA}^2$). In addition, the average chain length (L) for the lipid in the outer monolayer ($21 \text{ \AA}$) is longer than that in the inner monolayer ($16 \text{ \AA}$). These packing asymmetries are caused by the higher degree of surface curvature of the inner monolayer relative to the outer monolayer in a small vesicle with a radius of approximately $100 \text{ \AA}$. Similar conclusions have also been drawn for dipalmitoyl phosphatidylcholine vesicles.

The monolayer packing asymmetry in the highly curved bilayer, though simple and clear, needs to be considered seriously if the membrane structure and dynamics are to be inferred from NMR data obtained from sonicated membrane vesicles.

2.2 Comparison with Phospholipid Packings of Hexagonal Phases

From the geometric point of view, the phospholipid packing of the inner monolayer of sonicated membrane vesicles is similar to that of the inverted hexagonal H_{II} phase, whereas the packing of the outer monolayer is similar to that of hexagonal H_1 phase. Since the segmental order parameters in the acyl chain of both hexagonal H_1 and H_{II} phases have been measured by solid state ^2H NMR and compared to those of lamellar phase,³ it is instructive to make a comparison between the packing constraints of the hexagonal $\text{H}_1/\text{H}_{\text{II}}$ phases and the

Figure 1 Cross section of vesicle bilayer defining the three radial parameters R_a , R_b , and R_c used in the lipid packing analysis. The two shaded areas represent hydration layers of sonicated egg phosphatidylcholine vesicles. The distances L_o and L_i represent the monolayer thickness of the phospholipid located in the outer and inner halves of the vesicles, respectively. The average area/molecule is shown schematically as the section occupied by the lipid molecules, the values for which are described in the text

Figure 2 Geometric comparison between the phospholipids located in the inverted hexagonal H_{II} phase (a) and the inner monolayer of sonicated membrane vesicles (b). The radial parameters shown for the inverted hexagonal H_{II} phase are subject to variation with an estimated deviation of 2 Å.³ The values for the cross-sectional areas at the lipid/water interface, A_α , and at the end of the acyl chain, A_ω , for the inner monolayer of vesicle can be found in the text and Figure 1. The values of A_ω/A_α , and thus the geometric packing constraints, for the two systems are found to be similar

outer/inner monolayers based on their aggregate geometry. The main difference between these two lipid systems is that the curvature of the H_I/H_{II} phases distributes on a cylindrical surface, whereas the curvature of the outer/inner monolayers distributes on a spherical surface.

As depicted in Figure 2, quantitative comparison can be made for the packing constraint between the inner monolayer of sonicated membrane vesicles and the reverse hexagonal H_{II} phase. By using the surface area values obtained in Figure 1, the ratio of the cross-sectional areas at the end of the acyl chains, A_ω , and at the lipid/water interface, A_α , for the inner monolayer of vesicles can be found to be about 1.6. With the available radial parameters of the reverse hexagonal H_{II} phase, similar A_ω/A_α values ranging from 1.7–2.0 are obtained. This simple geometrical calculation, though crude because of the uncertainty in defining the headgroup region, illustrate that packing constraints for the two monolayers of the sonicated membrane vesicles can be similar to those of hexagonal phases although sonicated membrane vesicles have a larger radius of curvature. It is important to note that the surface area ratio for the cylindrical structure depends only on the first order of the radius. To a first approximation, one can estimate the effect of sonication on the molecular order of fatty acyl chains in the two monolayers by using the values determined from the hexagonal H_I/H_{II} phases. It will become clear that the NMR data obtained from sonicated membrane vesicles are indeed consistent with the above notion.

3 STRUCTURE AND DYNAMICS OF PHOSPHATIDYLCHOLINE IN VESICLES

Due to the asymmetric packing arrangement, the curvature affects the polar headgroup and fatty acyl chain regions of the phosphatidylcholine in vesicles differently. Therefore, our discussion in this section will be divided into two parts, keeping in mind that each region of the phospholipid molecule may be located either at the inner monolayer or at the outer monolayer.

Figure 3 ^{19}F NMR spectra of ^{19}F -labeled phosphatidylcholine in sonicated membrane vesicles at 282.4 MHz and 29 °C. The assignments for the resonances from molecules located at the inner and outer monolayers of vesicles are shown for ^{19}F -labeled phospholipid at the 4- and 8-positions. The linewidths obtained from the inner and outer monolayers differ approximately by a factor of 2

3.1 Fatty Acyl Chain Region

The simplest physical model to account for the NMR results obtained for the fatty acyl chain region was initiated by Chan and co-workers and developed further by many others.^{2,7} Basically, there are at least four motions of phospholipids in sonicated membrane vesicles: (i) chain reorientation (wobbling); (ii) chain isomerization (*trans*–*gauche* isomerization); (iii) lateral diffusion; and (iv) vesicle tumbling. Although different research groups may emphasize different parts of the motions or even introduce new types of motion,⁷ these four types of motion provide an adequate foundation for the treatment of NMR data obtained from sonicated membrane vesicles. (A collection of the references on the controversial issue of fatty acyl chain packing has been given by Fenske and Cullis.⁸)

In order to illustrate how the monolayer packing asymmetry and the aforementioned four types of motion can be considered in the NMR studies of sonicated membrane vesicles, we discuss results obtained from phosphatidylcholine vesicles labeled with a C^{19}F_2 group in the 4-, 8-, or 12-positions of the 2-acyl chain.⁹

^{19}F NMR spectra of sonicated unilamellar vesicles differ dramatically from those of lamellae. Instead of axially symmetric powder spectra, two overlapping Lorentzian resonances with different linewidths are observed (Figure 3). By applying a suitable shift reagent, it can be shown that the two signals originate from labeled phospholipids located at the inner and outer monolayers of the vesicles. Since both ^{19}F chemical shift anisotropy (CSA) and homonuclear dipolar interaction (DD) are averaged to zero on a timescale of 10^{-5} – 10^{-6} s, the narrow lines may simply result from averaging of the powder spectra by the isotropic tumbling of the spherical vesicles.^{10,11}

To relate the ^{19}F NMR spectra of vesicles and of multilamellar dispersions, we define a correlation time, τ_v , describing the tumbling of the entire vesicle in the solution and diffusion of the lipids around the surface of the vesicle

with correlation times, τ_r and τ_d :

$$\tau_v^{-1} = \tau_r^{-1} + \tau_d^{-1} \quad (5)$$

If the Stokes–Einstein results apply to the vesicle, an assumption validated by hydrodynamic measurements, the defined correlation times for the lipid located in the two monolayers can be rewritten as follows:

$$\tau_{o,i}^{-1} = kT/8\pi R_o^3 \eta + D/R_{o,i}^2 \quad (6)$$

where R_o is the outer vesicle radius, R_i is the inner vesicle radius, η the solvent viscosity, and D the lateral diffusion coefficient of the lipid molecules. The values of R_o and R_i can be taken from those of R_c and R_a , respectively, except that a hydration layer of approximately 6 Å should be included. By substituting appropriate values of η (1 cP) and D ($10^{-8} \text{ cm}^2 \text{ s}^{-1}$), the effective correlation time, τ_o , for the outer monolayer is about 10^{-6} s at room temperature. Note that the deduced correlation time depends on the cube of the radius. However, it depends linearly on the rate of lipid lateral diffusion. The second term in the right-hand side of Equation (6) will only slightly decrease the deduced correlation time and therefore the measured linewidth by about 10–20%, depending on whether the lipid is located in the outer or inner monolayer.¹⁰

The effective correlation time can also be calculated from the experimental ^{19}F NMR linewidth of the vesicles, assuming that other contributions to the linewidth from T_1 and DD (less than 10%) can be neglected, as follows:

$$\Delta\nu_{1/2}(\text{CSA}) = 1/(\pi T_2) = (16\pi/45)(\Delta\nu_{\text{CSA}})^2 \tau_v \quad (7)$$

Using the CSA value obtained from the multilamellar liposomes¹² and taking the F-labeled phospholipid at the 8-position as an example, the effective correlation time for the lipid located in the outer monolayer has been calculated to be $4 \times 10^{-7} \text{ s}$. This is about a factor of two smaller than the value estimated from the tumbling motion of sonicated membrane vesicles. Considering the approximation used in the calculation, the agreement between the experimental result and the theoretical prediction is, indeed, remarkable.

A further reduction of the linewidth for the ^{19}F NMR signal obtained from the F-labeled phospholipid located at the inner monolayer is detected as shown in Figure 3. Depending on the labeled position and the temperature, the reduction factor as compared to the outer monolayer ranges from two to three. A similar degree of reduction for the ^1H NMR linewidth obtained from the phospholipid fatty acyl chain in the inner monolayer has also been observed at 500 MHz.¹³ This could be due to the smaller radius of the inner monolayer, resulting in more effective modulation of the linewidth by phospholipid lateral diffusion,⁷ and also to the asymmetric packing of phospholipid in the inner monolayer, resulting in the reduced order parameter profile.² The order parameter for the inverse hexagonal H_{II} phase of perdeuterated phosphatidylethanolamine at the 8-labeled position, for instance, is found to be reduced by approximately 30% to 50% as compared to that of the lamellar phase.³ Since the linewidth depends on the square of the order parameter, one would expect a reduction by a factor of two for the linewidth of the inner monolayer as compared with that of the outer monolayer.

It has been well established from the temperature and frequency dependence of T_1 measurements by ^1H , ^2H , and

^{13}C NMR in lipid bilayers that two or more characteristic correlation times must exist for the fatty acyl chain motion.² For simplicity, one can assume that the observed T_1^{-1} is the sum of two independent contributions:

$$T_1^{-1} = T_{1f}^{-1} + T_{1s}^{-1} \quad (8)$$

where T_{1f}^{-1} indicates the contribution from relatively fast motion and T_{1s}^{-1} is the contribution from slower motion. Much effort has been made to characterize the motional modes responsible for the observed temperature and frequency dependence of T_1^{-1} .

It is generally agreed that the fast internal *trans*–*gauche* isomerization dynamics in the phospholipid acyl chain dominate the temperature dependence of T_1^{-1} . Assuming the applicability of an isotropic model for the chain isomerization, in the short correlation time range (i.e., $\omega_o \tau_c \ll 1$), the short correlation times are found to be about 10^{-10} s .

Studies of the frequency dependence of T_1^{-1} have allowed the characterization of slow motions in sonicated membrane vesicles. By analyzing the T_1^{-1} dispersion of ^2H NMR relaxation data, it has been suggested that restricted chain reorientation, or the wobbling motion of the phosphatidylcholine molecules, is responsible for the frequency dependence in the range of 10–100 MHz. The vesicle T_1^{-1} dispersion of ^2H NMR relaxation data below 10 MHz is, however, due to vesicle tumbling and lipid lateral diffusion.⁷ Therefore, chain reorientation, lipid lateral diffusion, and vesicle tumbling are three major types of motion responsible for slow motions in sonicated membrane vesicles.

In the following, we address the question as to which part of the motion, slow or fast, is perturbed by the curvature of the sonicated membrane vesicles.

The value of $T_{1\rho}$, but not of T_1 , has been found to be different for ^{19}F NMR resonances obtained from ^{19}F -labeled phospholipids located in the inside and outside monolayers of sonicated membrane vesicles.⁹ When $T_{1\rho}$ is measured in the presence of an off-resonance magnetic field, the motions sensitive to the effective field at low frequency, rather than stationary field at high frequency, are monitored. The result indicates that slow motions are responsible for the perturbed packing of fatty acyl chain located in the inner monolayer of vesicles. Since the fast motion (10^{-10} s) has been attributed primarily to *trans*–*gauche* isomerization of the lipid acyl chain, sonication apparently has not substantially changed the isomerization motion along the fatty acyl chain.

The effective correlation time determined by ^{19}F off-resonance $T_{1\rho}$ measurement is approximately 10^{-7} s , almost an order of magnitude lower than the effective correlation time estimated from the vesicle tumbling motion. A motion with similar correlation time has also been detected by studying the spin relaxation of ^1H -coupled ^{13}C spectra of fatty acids in sonicated membrane vesicles.¹⁴ Since restricted chain reorientation has been suggested to dominate the corresponding T_1^{-1} frequency dependence, it is tempting to suggest that the effect of sonication on the dynamics of phospholipid in vesicles is to increase the amplitude of chain reorientation on this timescale.

3.2 Polar Headgroup Region

The surface area of molecules in the outer monolayer is larger than that in the inner monolayer. The surface area

of the inner monolayer is similar to the surface area of a planar bilayer in the liquid crystalline state, while the surface area of the outer monolayer is somewhat expanded by curvature (Figure 1). A simple geometrical consideration would show that the average lipid–lipid distances in the headgroup region are stretched almost 1 Å further apart in the outer monolayer. Such an expansion would unquestionably influence the electrostatic interactions of the headgroup in the outer monolayer and therefore the conformation of the polar headgroup. Three examples cited here illustrate how temperature and vesicle size can differently affect the inner and outer monolayers in the phosphocholine headgroup region.

The organization of the zwitterionic phosphocholine headgroup has been studied by $^{31}\text{P}\{^1\text{H}\}$ NOE and ^{31}P NMR T_1 relaxation of sonicated membrane vesicles.¹⁵ Phosphatidylcholine headgroup packing has been found to consist of the positively charged quaternary amines of each lipid associating with the negatively charged phosphates of adjacent neighbors. In other words, the charged pair of the phosphocholine lies approximately along the plane of bilayer surface. Quantitative analysis of the NOE has suggested that the distance between intermolecular charged pairs is less than 3 Å. It should be pointed out that the monolayer packing asymmetry in sonicated membrane vesicles was not considered in these studies.

Phosphorus-31 NMR signals of the inner and outer monolayer in sonicated membrane vesicles can be studied by applying shift reagents.¹⁶ Temperature-dependent ^{31}P NMR T_1 studies have shown the existence of a distinct minimum relaxation time constant for the two monolayers. They have also revealed a very complicated picture, which suggests the need to reconsider the quantitative analysis of NOE. Nevertheless, ^{31}P NMR temperature-dependent studies of T_1 show that the position of the T_1 minimum for the inner monolayer was 9°C higher than that of the outer monolayer, indicating a higher level of motional restriction for the inner monolayer.

The ^1H NMR signals of sonicated membrane vesicles at a magnetic field of 7 T or higher show easily distinguishable resonances due to the phosphatidylcholine polar headgroup moiety $-\text{N}(\text{CH}_3)_3$ located in the two monolayers (Figure 4).¹⁷ Local magnetic effects due to headgroup organization are the important determinant of the difference in the NMR chemical shift between the inner and outer monolayer of vesicles. A difference in headgroup organization may be a result of a variation in the intermolecular electrostatic interactions of the zwitterionic headgroup.¹⁸

The two resolvable signals of the phosphocholine provide a simple tool for the investigation of the structure and dynamics of the polar headgroup in the two monolayers of sonicated membrane vesicles. In the following discussion we show how this phenomenon can be explained by the monolayer packing asymmetry for the polar headgroup region.

Figure 4 shows the choline N -methyl portion, $-\text{N}(\text{CH}_3)_3$, of the ^1H NMR spectra of sonicated distearoyl phosphatidylcholine vesicles at various temperatures. The chemical shift difference between the inner and outer choline N -methyl resonances increases abruptly as the temperature is lowered to the phospholipid phase transition temperature of 50°C. Careful analysis of the spectra has revealed that the changes result mainly from the low-frequency shift of the inner monolayer resonance.¹⁷ Therefore, at the phase transition, there is a change in the organization of the inner monolayer headgroup which does not occur for the outer monolayer headgroup.

Figure 4 Choline N -methyl portion of the 360 MHz ^1H NMR spectrum of sonicated membrane vesicles at various temperatures (°C). Resonances due to molecules on the inner and outer monolayers of the vesicles are indicated by arrows. (Reproduced by permission of Elsevier Science Publishers from K. E. Eigenberg and S. I. Chan *Biochim. Biophys. Acta*, 1980, **599**, 330)

In the liquid crystalline state, the conformation of the inner monolayer headgroups remains unperturbed by curvature since the inner headgroup area remains roughly the same as in a planar membrane. However, in the gel state, its organization is expected to change due to the reduced surface area, and thus the altered electrostatic interactions, at temperatures below the lipid phase transition. This effect is reflected in the abrupt change of the inner monolayer ^1H NMR chemical shift of $-\text{N}(\text{CH}_3)_3$. The corresponding outer monolayer signal remains similar, presumably because the packing of the headgroup in the outer monolayer is still expanded by the outwardly curved surface in small vesicles.

The experiments discussed so far provide a consistent picture to explain the available data regarding the packing arrangements of both the polar headgroup and fatty acyl chain regions of sonicated membrane vesicles. Because of the opposite packing constraints in the headgroup and fatty acyl chain region, one observes a reduced molecular order, or a perturbed packing, for the polar headgroup located in the outer monolayer and for the fatty acyl chain located in the inner monolayer. In the following discussion we provide another example to suggest that, analogous to the study of the fatty acyl chain region, the perturbed packing of the phosphatidylcholine headgroup in the outer monolayer can also be monitored by studying the linewidths of its NMR signal.

Sonication of the cholesterol/phospholipid dispersions produces small unilamellar vesicles with radii slightly different from single component phosphatidylcholine vesicles. Followed by gel filtration, a homogeneous population of vesicles with diameters ranging from 220 Å to 320 Å can be prepared for NMR investigation.¹⁹

Figure 5 Dependence of the ^1H NMR linewidths of *N*-methyl protons as a function of vesicle radius. The vesicles with designated radii were prepared by sonication of cholesterol/egg phosphatidylcholine (squares) and cholesterol/lyso phosphatidylcholine (circles) dispersions at known compositions. The linewidths obtained from phospholipid in the inner monolayer can be empirically fitted by the cube of the radius of the vesicles. The open and solid symbols represent the linewidth estimated from the NMR signals of the inner and outer monolayers, respectively

Figure 5 shows the ^1H NMR linewidth obtained from the *N*-methyl proton located in the inner and outer monolayers of sonicated cholesterol/phospholipid vesicles as a function of vesicle size. The ^1H NMR linewidth of the inner monolayer increased almost threefold when the diameter of the vesicles increased from 220 Å to 320 Å. According to Equation (7), the linewidth depends roughly on the cube of the vesicle radius. Increasing the vesicle size by 50% would increase the NMR linewidth by a factor of three. Therefore, the variation of the ^1H NMR linewidth of the choline *N*-methyl proton in the inner monolayer can be explained by considering the change in vesicle size. Qualitatively similar effects have been observed by ^{31}P NMR studies of the polar headgroup in larger vesicles.²⁰

The ^1H NMR linewidths obtained from *N*-methyl protons located in the outer monolayers of sonicated vesicles are several-fold smaller than those obtained from the inner monolayers. In addition, they remain relatively constant in the vesicle preparations studied. This indicates that additional motion is present for the phosphocholine headgroup of the lipid molecules located in the outer monolayers. This must be due to the perturbed packing of polar headgroup in the outer monolayers because more effective modulation of the linewidth by phospholipid lateral diffusion can only occur in the inner monolayers.

In conclusion, the linewidth of the *N*-methyl group appears to be a function of the vesicle radius and is also dependent on whether the molecules sit in the inner or outer monolayer. Based on this observation, it is impossible to obtain the same order parameter for the phospholipid molecule in the small vesicles and in the planar bilayer if analysis of the NMR linewidth is undertaken by considering only one NMR signal which actually contains both sharp and broad components. It also explains why the detected NMR linewidth of the fatty acyl chain in small vesicles was markedly smaller than that

estimated from the second moment of the planar bilayer and, at the same time, modulated by the solvent viscosity.^{2,11}

4 OTHER LIPID SYSTEMS

Our discussion on the structure and dynamics of sonicated membrane vesicles has mainly concentrated on phosphatidylcholine molecules. Biological membranes actually contain many lipid molecules such as cholesterol, phosphatidylethanolamine, phosphatidylserine, sphingomyelin, cerebrosides, etc. With the advent of solid state NMR spectroscopy, especially broadband ^2H NMR and magic angle spinning ^{13}C NMR, most of the structural and dynamic information concerning various types of lipid molecules are now obtained from unsonicated lipid membranes. We are therefore left with the question whether the sonicated membrane vesicle can still provide a useful model membrane system for NMR studies of other lipid molecules.²¹

Although we have discussed the polar headgroup and fatty acyl chain regions quite extensively, little has been said about the effect of curvature on the pivotal interfacial region of the lipid molecule. One attractive approach might be studies of exchangeable protons of sphingolipids in sonicated membrane vesicles.²² By studying the exchange rate of amide protons in several sphingomyelin-containing sonicated membrane vesicles as a function of pH, the existence of intermolecular hydrogen bonding at the interfacial region has been inferred.

The kinetics of proton exchange for phosphatidylethanolamine in sonicated mixed membrane vesicles has also been studied.²³ This may provide information on the mechanism responsible for proton transport in and to membrane surfaces. It will be interesting to ascertain whether curvature significantly changes the kinetics of these processes.

Finally, there is a great deal of interest in the asymmetric distribution of lipids in both model and biological membranes. With the availability of lipid transfer proteins, small unilamellar vesicles with synthetic lipid molecules in designated monolayers can be prepared. Sonicated membrane vesicles will no doubt continue to be useful in future NMR studies of membrane structure and dynamics.

1 INTRODUCTION

The last few years have seen a quantum jump in both the accuracy of the determination and in the size of protein structures that can be determined by NMR.¹ Thus it is now possible to determine the structures of proteins in the 15–25 kDa range at a resolution comparable to 0.2 nm resolution for crystal structures.² This advance is attributable to the development of three- and four-dimensional heteronuclear NMR techniques which circumvent problems associated with chemical shift overlap and degeneracy, on the one hand, and large linewidths on the other.^{1,3–5} In this article, we summarize some of these developments and illustrate their application to the structure determination of interleukin-1 β (IL-1 β),⁶ a complex of calmodulin with a target peptide,⁷ and a complex of the DNA binding domain of the transcription factor GATA-1 with its cognate DNA target site.⁸

2 GENERAL STRATEGY FOR THE DETERMINATION OF THREE-DIMENSIONAL STRUCTURES OF LARGER PROTEINS AND PROTEIN COMPLEXES BY NMR

The main source of geometric information used in protein structure determination lies in the nuclear Overhauser effect

(NOE) which can be used to identify protons separated by less than 0.5 nm.⁹ This distance limit arises from the fact that the NOE is proportional to the inverse sixth power of the distance between the protons. Hence the NOE intensity falls off very rapidly with increasing distance between proton pairs. Despite the short range nature of the observed interactions, the short approximate interproton distance restraints derived from the NOE measurements can be highly conformationally restrictive, particularly when they involve residues that are far apart in the sequence but close together in space.

The power of NMR over other spectroscopic techniques results from the fact that every proton gives rise to an individual resonance in the spectrum which can be resolved by higher (i.e. two, three and four) dimensional techniques. Bearing this in mind, the principles of structure determination by NMR can be summarized very simply by the scheme depicted in Figure 1. The first step is to obtain sequential resonance assignments using a combination of through-bond and through-space correlations; the second step is to obtain stereospecific assignments at chiral centers and torsion angle restraints using three-bond scalar couplings combined with intrasidue and sequential interresidue NOE data; the third step is to identify through-space connectivities between protons separated by less than 0.5 nm and, finally, the fourth step involves calculating three-dimensional structures on the basis of the amassed interproton distance and torsion angle restraints using one or more of a number of algorithms^{10–12} such as distance geometry and/or simulated annealing. It is not essential to assign all the NOEs initially. Indeed, many may be ambiguous and several possibilities may exist for their assignments. However, once a low-resolution structure has been calculated from a subset of the NOE data which can be interpreted unambiguously, it is then possible to employ iterative methods to resolve the vast majority of ambiguities. Consider, for example, an NOE cross peak which could be attributable to a through-space interaction between either protons A and B or between protons A and C. Once a low-resolution structure is available it is usually possible to discriminate between these two possibilities. Thus, if protons A and C are significantly greater than 0.5 nm apart while protons A and B are less than 0.5 nm apart, it is clear that the cross peak must arise from an NOE between protons A and B.

The quality of an NMR protein structure determination increases as the number of restraints increase.^{1,4,13–15} This progression in coordinate precision is illustrated in Figure 2 which shows four generations of structures, ranging from the first generation which simply provides a picture of the polypeptide fold with little detail, to the fourth generation which is broadly equivalent to a 0.2 nm resolution X-ray structure.

2.1 Sequential Resonance Assignment

Conventional sequential resonance assignment relies on two-dimensional homonuclear ^1H – ^1H correlation experiments to identify amino acid spin systems coupled with two-dimensional ^1H – ^1H NOE experiments to identify sequential connectivities along the backbone of the type $\text{C}^\alpha\text{H}(i)$ – $\text{NH}(i + 1, 2, 3, 4)$, $\text{NH}(i)$ – $\text{NH}(i \pm 2)$ and $\text{C}^\alpha\text{H}(i)$ – $\text{C}^\beta\text{H}(i + 3)$.^{16,17} This methodology has been successfully applied to proteins of less than 100 residues. For larger proteins, the

Figure 1 Summary of the general strategy employed to solve three-dimensional structures of macromolecules by NMR. (Adapted from G. M. Clore and A. M. Gronenborn, *Science*, 1991, **252**, 1390)

spectral complexity is such that two-dimensional experiments no longer suffice, and it is essential to increase the spectral resolution by increasing the dimensionality of the spectra.¹⁸ In some cases it is still possible to apply the same strategy by making use of three-dimensional heteronuclear (^{15}N or ^{13}C) edited experiments to increase the spectral resolution, as illustrated in Figure 3.^{19–22} In many cases, however, numerous ambiguities still remain and it is advisable to adopt a sequential assignment strategy based solely on well defined heteronuclear scalar couplings.^{3,5,23–25} The double and triple resonance experiments that we currently use, and the correlations that they demonstrate, are summarized in Table 1. With the advent of pulse field gradients to eliminate undesired coherence transfer pathways,²⁶ it is now possible to employ only two-step phase cycles without any loss in sensitivity (other than that due to the reduction in measurement time) such that each three-dimensional experiment can be recorded in as little as 7 h. In most cases, however, signal-to-noise ratio requirements necessitate 1–3 days of measuring time, depending on the experiment.

2.2 Stereospecific Assignments and Torsion Angle Restraints

It is often possible to obtain stereospecific assignments of β -methylene protons on the basis of a qualitative interpretation of the homonuclear $^3J(\alpha, \beta)$ coupling constants and the intraresidue NOE data involving the NH, C^αH and C^βH protons.^{27,28} A more rigorous approach, which also permits one to obtain ϕ , ψ , and χ_1 restraints, involves the application of a conformational grid search of ϕ, ψ, χ_1 space on the basis of the homonuclear $^3J(\text{N}-\alpha, \text{H})$ and $^3J(\alpha, \beta)$ coupling constants (which are related to ϕ and χ_1 , respectively), and the intraresidue and sequential ($i \pm 1$) interresidue NOEs involving the NH, C^αH and C^βH protons.^{29,30} This

information can be supplemented by the measurement of heteronuclear $^3J(\text{N}, \text{H}-\beta)$ and $^3J(\text{CO}, \text{H}-\beta)$ couplings which are also related to χ_1 .³¹ Stereospecific assignment of valine methyl groups can be made on the basis of $^3J(\text{C}-\gamma, \text{CO})$ and $^3J(\text{N}, \text{C}-\gamma)$ couplings,³¹ as well as on the basis of the pattern of intraresidue NOEs involving the NH, C^αH and C^γH protons.³² Finally, stereospecific assignments of leucine methyl groups can be made on the basis of heteronuclear $^3J(\text{C}-\delta, \text{C}-\alpha)$ and $^3J(\text{C}-\delta, \text{H}-\beta)$ couplings³¹ in combination with the pattern of intraresidue NOEs, provided that the stereospecific assignment of the β -methylene protons and the χ_1 rotamer have been previously determined.³³

2.3 Assignment of Through-space Proton-Proton Interactions within a Protein

While the panoply of three-dimensional heteronuclear experiments is sufficient for the purposes of spectral assignment, yet further increases in resolution are required for the reliable identification of NOE through space interactions. This can be achieved by extending the dimensionality still further to four dimensions.³⁴ This is illustrated in Figure 4. Consider a simple two-dimensional spectrum demonstrating 11 cross peaks from aliphatic resonances to a single NH resonance position. In the two-dimensional spectrum it is impossible to ascertain whether this involves one NH proton or many. Extending the spectrum to three dimensions by separating the NOE interactions according to the ^{15}N chemical shift of the nitrogen attached to each amide proton reveals that there are three NH protons involved. The identity of the originating aliphatic protons, however, is only specified by their proton chemical shifts. Yet the extent of spectral overlap in the aliphatic region of the spectrum vastly exceeds that in the amide region. This can be resolved by adding a further dimension in which each plane of the three-dimensional spectrum now constitutes a cube in the

1st Generation
 ~ 7 restraints per residue
 rmsd: 0.15 nm for backbone atoms
 0.20 nm for all atoms
 Example: purothionin

2nd Generation
 ~ 10 restraints per residue
 rmsd: 0.09 nm for backbone atoms
 0.12 nm for all atoms
 Example: BDS-I

3rd Generation
 ~ 13 restraints per residue
 rmsd: 0.07 nm for backbone atoms
 0.09 nm for all atoms
 Example: BDS-I

4th Generation
 ~ 16 restraints per residue
 rmsd: 0.04 nm for backbone atoms
 0.09 nm for all atoms
 ≤0.05 nm for ordered side chains
 Example: Interleukin-8

Figure 2 Illustration of the progressive improvement in the precision and accuracy of NMR structure determinations with increasing number of experimental restraints. All the structures have been calculated using the hybrid distance geometry, simulated annealing method, and in each case the NOE derived interproton distance restraints have been grouped into the three broad ranges: 0.18–0.27, 0.18–0.33, and 0.18–0.5 nm, corresponding to strong, medium and weak NOEs, respectively. (Adapted from G. M. Clore and A. M. Gronenborn, *Science*, 1991, **252**, 1390)

four-dimensional spectrum edited by the ^{13}C shift of the carbon atom attached to each aliphatic proton. In this manner, each ^1H – ^1H NOE interaction is specified by four chemical shift coordinates, the two protons giving rise to the NOE and the heavy atoms to which they are attached. The resolving power of four-dimensional heteronuclear-edited NOE spectroscopy is illustrated in Figure 5.

Because the number of NOE interactions present in each two-dimensional plane of a four-dimensional $^{13}\text{C}/^{15}\text{N}$ or $^{13}\text{C}/^{13}\text{C}$ edited NOESY spectrum is so small, the inherent resolution in a four-dimensional spectrum is extremely high, despite the low level of digitization. Indeed, spectra with equivalent resolution can be recorded at magnetic field strengths considerably lower than 600 MHz, although this

Figure 3 Comparison of the NH- $C^{\alpha}H/C^{\beta}H$ region of a two-dimensional ^{15}N -edited NOESY spectrum (a) with that of a single plane taken from the three-dimensional ^{15}N -edited NOESY spectrum of interleukin-1 β (b), illustrating the increase in spectral resolution afforded by increasing the dimensionality from two to three. Table 1 Summary of Correlations Observed in the Three-dimensional Double and Triple Resonance Experiments used for Sequential and Side-Chain Assignments in our Laboratory

Experiment	Correlation	J Coupling ^a
^{15}N edited HOHAHA	$C^{\alpha}H(i) - ^{15}N(i) - NH(i)$	$^3J(N-\alpha, H)$
	$C^{\beta}H(i) - ^{15}N(i) - NH(i)$	$^3J(N-\alpha, H)$ and $^3J(\alpha, \beta)$
HNHA	$C^{\alpha}H(i) - ^{15}N(i) - NH(i)$	$^3J(N, H)$
H(CA)NH	$C^{\alpha}H(i) - ^{15}N(i) - NH(i)$	$^1J(N, C-\alpha)$
	$C^{\alpha}H(i-1) - ^{15}N(i) - NH(i)$	$^2J(N, C-\alpha)$
HNCA	$^{13}C^{\alpha}(i) - ^{15}N(i) - NH(i)$	$^1J(N, C-\alpha)$
	$^{13}C^{\alpha}(i-1) - ^{15}N(i) - NH(i)$	$^2J(N, C-\alpha)$
HN(CO)CA	$^{13}C^{\alpha}(i-1) - ^{15}N(i) - NH(i)$	$^1J(N, CO)$ and $^1J(C-\alpha, CO)$
HNCO	$^{13}CO(i-1) - ^{15}N(i) - NH(i)$	$^1J(N, CO)$
HCACO	$C^{\alpha}H(i) - ^{13}C^{\alpha}(i) - ^{13}CO(i)$	$^1J(C-\alpha, CO)$
HCA(CO)N	$C^{\alpha}H(i) - ^{13}C^{\alpha}(i) - ^{15}N(i+1)$	$^1J(C-\alpha, CO)$ and $^1J(N, CO)$
CBCA(CO)NH	$^{13}C^{\beta}(i-1)/^{13}C^{\alpha}(i-1) - ^{15}N(i) - NH(i)$	$^1J(C-\alpha, CO)$, $^1J(N, CO)$ and $^1J(C, C)$
CBCANH	$^{13}C^{\beta}(i)/^{13}C^{\alpha}(i) - ^{15}N(i) - NH(i)$	$^1J(N, C-\alpha)$ and $^1J(C, C)$
	$^{13}C^{\beta}(i-1)/^{13}C^{\alpha}(i-1) - ^{15}N(i) - NH(i)$	$^2J(N, C-\alpha)$ and $^1J(C, C)$
HBHA(CO)NH	$C^{\beta}H(i-1)/C^{\alpha}H(i-1) - ^{15}N(i) - NH(i)$	$^1J(C-\alpha, CO)$, $^1J(N, CO)$ and $^1J(C, C)$
HBHANH	$C^{\beta}H(i)/C^{\alpha}H(i) - ^{15}N(i) - NH(i)$	$^1J(N, C-\alpha)$ and $^1J(C, C)$
	$C^{\beta}H(i-1)/C^{\alpha}H(i-1) - ^{15}N(i) - NH(i)$	$^2J(N, C-\alpha)$ and $^1J(C, C)$
C(CO)NH	$^{13}C^j(i-1) - ^{15}N(i) - NH(i)$	$^1J(C-\alpha, CO)$, $^1J(N, CO)$ and $^1J(C, C)$
H(CCO)NH	$H^j(i-1) - ^{15}N(i) - NH(i)$	$^1J(C-\alpha, CO)$, $^1J(N, CO)$ and $^1J(C, C)$
HCCH-COSY	$H^j - ^{13}C^j - ^{13}C^{j\pm 1} - H^{j\pm 1}$	$^1J(C, C)$
HCCH-TOCSY	$H^j - ^{13}C^j \dots ^{13}C^{j\pm n} - H^{j\pm n}$	$^1J(C, C)$

^aIn addition to the couplings indicated, all the experiments make use of the $^1J(C, H)$ (≈ 140 Hz) and/or $^1J(N, H)$ (≈ 95 Hz) couplings. The values of the couplings employed are as follows: $^3J(N-\alpha, H) \approx 3-10$ Hz, $^1J(C, C) \approx 35$ Hz, $^1J(C-\alpha, CO) \approx 55$ Hz, $^1J(N, CO) \approx 15$ Hz, $^1J(N, C-\alpha) \approx 11$ Hz, $^2J(N, C-\alpha) \approx 7$ Hz.

Figure 4 Schematic illustration of the progression and relationship between two-, three-, and four-dimensional heteronuclear-edited NMR spectroscopy. (Adapted from G. M. Clore and A. M. Gronenborn, *Science*, 1991, **252**, 1390)

would obviously lead to a reduction in sensitivity. Furthermore, it can be calculated that four-dimensional spectra with virtual lack of resonance overlap and good sensitivity can be obtained on proteins with as many as 400 residues. Thus, once complete ^1H , ^{15}N , and ^{13}C assignments are obtained, analysis of four-dimensional $^{15}\text{N}/^{13}\text{C}$ and $^{13}\text{C}/^{13}\text{C}$ edited NOE spectra^{34–37} should permit the automated assignment of almost all NOE interactions.

3 APPLICATION OF THREE- AND FOUR-DIMENSIONAL NMR TO STRUCTURE DETERMINATION OF LARGER PROTEINS: THE STRUCTURE OF INTERLEUKIN-1 β

While the potential of heteronuclear three- and four-dimensional NMR methods in resolving problems associated with both extensive resonance overlap and large linewidths

is obvious, how does this new approach fare in practice? In this regard it should be borne in mind that resonance assignments are only a means to an end, and the true test of multidimensional NMR lies in examining its success in solving the problem which it was originally designed to tackle, namely the determination of high-resolution three-dimensional structures of larger proteins in solution.

The first successful demonstration of these new methods was the determination of the high-resolution solution structure of interleukin-1 β (IL-1 β), a cytokine of 153 residues and molecular weight 17.4 kDa, which plays a key role in the immune and inflammatory responses.⁶ At the time IL-1 β was 50% larger, in terms of the number of residues, than the previously largest protein structures solved by NMR, namely human³⁸ and *Escherichia coli*³⁹ thioredoxin which have 105 and 108 residues, respectively. Moreover, IL-1 β still represents one of the most highly refined and precise structures for proteins of this size solved by NMR.

Despite extensive analysis of two-dimensional spectra obtained at different pH values and temperatures, as well as

Figure 5 Example of the increase in spectral resolution afforded by four-dimensional $^{13}\text{C}/^{13}\text{C}$ -edited NOE spectroscopy, illustrated with IL-1 β . (a) $^1\text{H}(F_2)$ - $^1\text{H}(F_4)$ plane of the four-dimensional spectrum at $\delta^{13}\text{C}(F_1) = 44.3$ ppm and $\delta^{13}\text{C}(F_3) = 34.6$ ppm; the region between 1 and 2 ppm is boxed in and the arrow indicates the position of the Lys77 C^γH - C^βH NOE cross peak. (b) Two-dimensional ^1H - ^1H NOE spectrum between 1 and 2 ppm; the X marks the chemical shift position of the Lys77 C^γH - C^βH NOE cross peak seen in (a). (c, d) Positive and negative contours in the $^{13}\text{C}(F_1)$ - $^{13}\text{C}(F_3)$ plane of the four-dimensional spectrum at the ^1H chemical shift coordinates $\delta^1\text{H}(F_2) = 1.39$ ppm and $\delta^1\text{H}(F_4) = 1.67$ ppm corresponding to the Lys77 C^γH - C^βH NOE cross peak seen in (a) and the X mark shown in (b). Because extensive folding is employed, the ^{13}C chemical shifts are given by $x \pm n\text{SW}$, where x is the ppm value listed in the figure, n is an integer, and SW is the spectral width (20.71 ppm). Peaks folded an even number of times are of opposite sign to those folded an odd number of times. All the peaks in (a) are positive, except for the two indicated by an asterisk which are negative. (Adapted from G. M. Clore and A. M. Gronenborn, *Science*, 1991, **252**, 1390)

examination of two-dimensional spectra of mutant proteins, it did not prove feasible to obtain unambiguous ^1H assignment for more than about 30% of the residues of interleukin-1 β .²² Thus, any further progress could only be made by resorting to higher dimensionality heteronuclear NMR. The initial step involved the complete assignment of the ^1H , ^{15}N , and ^{13}C resonances of the backbone and side chains using

many of the double and triple resonance three-dimensional experiments listed in Table 1.^{22,40,41} In the second step, backbone and side-chain torsion angle restraints, as well as stereospecific assignments for β -methylene protons, were obtained by means of a three-dimensional systematic grid search of ϕ, ψ, χ_1 space.³⁰ In the third step, approximate interproton distance restraints between nonadjacent residues

were derived from analysis of three- and four-dimensional heteronuclear-edited NOE spectra. Analysis of the three-dimensional heteronuclear-edited NOE spectra alone was sufficient to derive a low-resolution structure on the basis of a small number of NOEs involving solely NH, C α H and C β H protons.⁴² However, further progress using three-dimensional NMR was severely hindered by the numerous ambiguities still present in these spectra, in particular for NOEs arising from the large number of aliphatic protons. Thus, the four-dimensional heteronuclear-edited NOE spectra proved to be absolutely essential for the successful completion of this task. In addition, the proximity of backbone NH protons to bound structural water molecules was ascertained from a three-dimensional ¹⁵N-separated ROESY spectrum which permits one to distinguish specific protein–water NOE interactions from chemical exchange with bulk solvent.⁴³ In this regard it should be emphasized that all the NOE data were interpreted in as conservative a manner as possible, and were simply classified into three distance ranges: 0.18–0.27, 0.18–0.33, and 0.18–0.50 nm, corresponding to strong, medium, and weak intensity NOEs, respectively.

With an initial set of experimental restraints in hand, three-dimensional structure calculations were initiated using the hybrid distance geometry–dynamical simulated annealing method.⁴⁴ A key aspect of the overall strategy lies in the use of an iterative approach whereby the experimental data are reexamined in the light of the initial set of calculated structures in order to resolve ambiguities in NOE assignments, to obtain more stereospecific assignments (e.g. the α -methylene protons of glycine and the methyl groups of valine and leucine) and torsion angle restraints, and to assign backbone hydrogen bonds associated with slowly exchanging NH protons as well as with bound water molecules. The iterative cycle comes to an end when all the experimental data have been interpreted.

The final experimental data set for IL-1 β comprised a total of 3146 approximate and loose experimental restraints made up of 2780 distance and 366 torsion angle restraints.⁶ This represents an average of about 21 experimental restraints per residue. If one takes into account that interresidue NOEs affect two residues, while intraresidue NOE and torsion angle restraints only affect individual residues, the average number of restraints influencing the conformation of each residue is approximately 33. Superpositions of the backbone atoms and selected side chains for 32 independently calculated structures are shown in Figures 6(b) and 6(d). All 32 structures satisfy the experimental restraints within their specified errors, display very small deviations from idealized covalent geometry, and have good nonbonded contacts. It can be seen that both the backbone and ordered side chains are exceptionally well defined. Indeed, the atomic root-mean-square (rms) distribution about the mean coordinate positions is 0.04 nm for the backbone atoms, 0.08 nm for all atoms, and 0.05 nm for side chains with $\leq 40\%$ of their surface (relative to that in a tripeptide Gly-X-Gly) accessible to solvent.⁶

The structure of IL-1 β itself resembles a tetrahedron and displays three-fold internal pseudosymmetry. There are 12 β -strands arranged in an exclusively antiparallel β -structure, and six of the strands form a β -barrel [seen in the front of Figure 6(a)] which is closed off at the back of the molecule by the other six strands. Each repeating topological unit is composed of 5 strands arranged in an antiparallel manner with respect to each other, and one of these units is shown in Figure 6(c).

Water molecules occupy very similar positions in all three topological units, as well as at the interface of the three units, and are involved in bridging backbone hydrogen bonds. Thus, in the case of the topological unit shown in Figure 6(c), the water molecule labeled W5 accepts a hydrogen bond from the NH of Phe112 in strand IX and donates two hydrogen bonds to the backbone carbonyls of Ile122 in strand X and Thr144 in strand XII. The packing of some internal residues with respect to one another, as well as the excellent definition of internal side chains, is illustrated in Figure 6(d). Because of the high resolution of the IL-1 β structure it was possible to analyze in detail side-chain–side-chain interactions involved in stabilizing the structure. In addition, examination of the structure in the light of mutational data permitted us to propose the presence of three distinct sites involved in the binding of IL-1 β to its cell surface receptor.⁶

4 COMBINING EXPERIMENTAL INFORMATION FROM CRYSTAL AND SOLUTION STUDIES: JOINT X-RAY AND NMR REFINEMENT

It is clear from the preceding discussion that NMR is a valid method, alongside X-ray crystallography, for determining high-resolution structures of small to medium sized proteins of less than about 35 kDa. IL-1 β offers an ideal system for comparing the results of NMR and X-ray crystallography as, in addition to the solution structure, there are three independently solved X-ray structures at 0.2 nm resolution of the same crystal form.^{45–47} The backbone atomic rms difference between the NMR and the X-ray structures is about 0.1 nm, with the largest differences being confined to some of the loops and turns connecting the β -strands.² Interestingly, however, the atomic rms distribution of the 32 calculated solution structures about their mean coordinate positions (about 0.04 nm for the backbone atoms, about 0.08 nm for all atoms, and about 0.05 nm for all atoms of internal residues) is approximately the same as the atomic rms differences between the three X-ray structures, indicating that the positional errors in the atomic coordinates determined by the two methods are similar.² Upon initial inspection, the X-ray structures appear to be incompatible with the NMR data, as manifested by a relatively large number of NOE and torsion angle violations and, conversely, the NMR structure fits the X-ray data poorly with an *R* factor of 40–50%. Because of the very different nature of the two methods, it is not immediately apparent that these discrepancies reflect genuine differences between the solution and X-ray structures or whether they reflect differences in the computational procedures employed. To analyze this in more detail we have developed a new method of structure determination in which the NMR and X-ray data are combined and used simultaneously in the structure refinement.⁴⁸ Using this approach we have shown that a model can readily be generated from a joint NMR/X-ray refinement which is compatible with the data from both techniques. Thus, there are only minimal violations of the NMR restraints (NOEs and torsion angles), the value of the crystallographic *R* factor is comparable to, if not better than, that derived from refinement against the crystallographic data alone, and the deviations from idealized covalent geometry are small. In addition, the *R* free⁴⁹ for the model refined with the NMR and

Figure 6 Solution structure of IL-1 β determined by three- and four-dimensional heteronuclear NMR spectroscopy. (a) Ribbon diagram of the polypeptide fold. (b) Superposition of the backbone (N, C α , and C) atoms of 32 simulated annealing structures calculated from the experimental NMR data. (c) Superposition of the backbone (N, C α , C, and O) atoms of one of the three repeating topological units, illustrating the position of tightly bound water at the interface of the three central strands of the unit. (d) Superposition of all atoms (excluding protons) for selected side chains. The diagram in (a) was made using the program MOLSCRIPT.¹⁰² The coordinates are from Clore et al.⁶ (PDB accession code 6IIB). (Adapted from G. M. Clore, P. T. Wingfield, and A. M. Gronenborn, *Biochemistry*, 1991, **30**, 2315)

X-ray restraints is smaller than that of the model obtained by conventional crystallographic refinement, indicating that the crystallographic phases obtained by the joint NMR/X-ray refinement are more accurate. Moreover, the few NMR observations that are still violated by the model serve as an indicator for genuine differences between the crystal and solution structures.

The implications of the joint NMR/X-ray refinement method to structural biology are of considerable significance. In particular, the full potential and future use of the method will be for structure determinations of multidomain proteins, for which only low-resolution X-ray data for the entire protein are available but for which detailed structural information may be obtained by NMR on the individual domains. Using the joint X-ray/NMR refinement approach in such cases will open the way to the study of proteins which may otherwise never be structurally accessible by either of the two methods alone.

5 STRUCTURE DETERMINATION OF PROTEIN–PEPTIDE AND PROTEIN–DNA COMPLEXES

Provided the ligand (e.g. a peptide, an oligonucleotide, or a drug) presents a relatively simple spectrum that can be assigned by two-dimensional methods, the most convenient strategy for dealing with protein–ligand complexes involves one in which the protein is labeled with ^{15}N and ^{13}C and the ligand is unlabeled (i.e. at natural isotopic abundance).⁵⁰ It is then possible to use a combination of heteronuclear filtering and editing to design experiments in which correlations involving only protein resonances, only ligand resonances, or only through-space interactions between ligand and protein are observed. These experiments are summarized in Table 2 and were first applied successfully to a complex of calmodulin with a target peptide from skeletal muscle myosin light chain kinase,⁷ and subsequently to the specific complex of the DNA binding domain of the transcription factor GATA-1 with its cognate DNA target site.⁸

5.1 The Structure of the Calmodulin–Target Peptide Complex

Calmodulin (CaM) is a ubiquitous Ca^{2+} binding protein of 148 residues which is involved in a wide range of cellular Ca^{2+} -dependent signaling pathways, thereby regulating the activity of a large number of proteins.⁵¹ The crystal structure of Ca^{2+} -CaM was solved a number of years ago.⁵² It is a dumb-bell shaped molecule with an overall length of about 6.5 nm and consisting of two globular domains, each of which contains two Ca^{2+} binding sites of the helix–loop–helix type, connected by a long, solvent exposed, rigid central helix some eight turns in length (residues 66–92). In solution, on the other hand, ^1H – ^{15}N NMR relaxation measurements have demonstrated unambiguously that the central helix is disrupted near its midpoint, with residues 78–81 adopting an essentially unstructured ‘random coil’ conformation which is so flexible that the N- and C-terminal domains of Ca^{2+} -CaM effectively tumble independently of each other.⁵⁸ Thus, in solution, the so-called ‘central helix’ is not a helix at all but is a ‘flexible tether’ the purpose of which is to keep the two domains in close proximity for binding to their target.

In order to understand the way in which Ca^{2+} -CaM recognizes its target sites, we set out to solve, in collaboration with Ad Bax, the solution structure of a complex of Ca^{2+} -CaM with a 26 residue peptide (known as M13) comprising residues 577–602 of the calmodulin binding domain of skeletal muscle myosin light chain kinase. The solution structure was determined on the basis of 1995 experimental NMR restraints including 133 interproton distance restraints between the peptide and the protein. The N-terminus (residues 1–5) and C-terminus (residues 147–148) of CaM, the tether connecting the two domains of CaM (residues 74–82), and the N-terminus (residues 1–2) and C-terminus (residues 22–26) of M13 were ill-defined by the NMR data and appear to be disordered in solution. The atomic rms distribution about the mean coordinate positions for the rest of the structure (i.e. residues 6–73 and 83–146 of CaM, and residues 3–21 of M13) is 0.1 nm for the backbone atoms and 0.14 nm for all atoms. Thus this structure represents a second generation

Table 2 Summary of Heteronuclear-filtered and -edited NOE Experiments used to Study Protein–Ligand Complexes Comprising a Uniformly $^{15}\text{N}/^{13}\text{C}$ Labeled Protein and an Unlabeled Ligand

Type of contact	Connectivity
<i>A Intramolecular protein contacts</i>	
4D $^{13}\text{C}/^{13}\text{C}$ -edited NOE in D_2O	$\text{H}(j) - ^{13}\text{C}(j) \cdots \text{H}(i) - ^{13}\text{C}(i)$
4D $^{15}\text{N}/^{13}\text{C}$ -edited NOE in H_2O	$\text{H}(j) - ^{15}\text{N}(j) \cdots \text{H}(i) - ^{13}\text{C}(i)$
3D $^{15}\text{N}/^{15}\text{N}$ -edited NOE in H_2O	$\text{H}(j) - ^{15}\text{N}(j) \cdots \text{H}(i) - ^{15}\text{N}(i)$

^aSimilar heteronuclear filtered two-dimensional correlation and Hartmann–Hahn spectra can also be recorded to assign the spin systems of the ligand.

structure in the classification of Clore and Gronenborn.¹ A stereoview showing a best fit superposition of the 24 calculated structures is shown in Figure 7(a).

The major conformational change in Ca^{2+} -CaM that occurs upon binding M13 involves an extension of the flexible tether (residues 78–81) in the middle of the ‘central’ helix of the solution structure of free Ca^{2+} -CaM to a long flexible loop extending from residues 74–81, flanked by two helices (residues 65–73 and 83–93), thereby enabling the two domains to come together, gripping the peptide rather like two hands capturing a rope. The hydrophobic channel formed by the two domains is complementary in shape to that of the peptide helix. This is clearly illustrated by the schematic ribbon drawings shown in Figures 7(b) and 7(c) which also serve to highlight the approximate two-fold pseudosymmetry of the complex. Thus, whereas the two domains of CaM are arranged in an approximately orthogonal manner to each other in the crystal structure of Ca^{2+} -CaM,⁵² in the Ca^{2+} -CaM-M13 complex they are almost symmetrically related by a 180° rotation about a two-fold axis. A large conformational change also occurs in the M13 peptide upon complexation from a random coil state to a well defined helical conformation. Indeed, the helix involves all the residues (3–21) of M13 that interact with CaM, while the N-terminus (residues 1–2) and C-terminus (residues 22–26) of the peptide which do not interact with CaM, remain disordered.

Upon complexation there is a decrease in the accessible surface area of CaM and M13 of 18.48 and 14.77 nm², respectively, which corresponds to a decrease in the calculated solvation free energy of folding⁵³ of 18 and 20 kcal mol⁻¹ (75–83 kJ mol⁻¹), respectively. This large decrease in solvation free energy would account for the very tight binding ($K_{\text{ass}} \approx 10^9 \text{ M}^{-1}$) of M13 to calmodulin. In addition, the accessible surface area of the portion of M13 (residues 3–21) in direct contact with CaM in the complex is only 4.94 nm² compared with an accessible surface of area 31.23 nm² for a random coil and 22.50 nm² for a helix. Thus, over 80% of the surface of the peptide in contact with CaM is buried.

In the view shown in Figure 7(b), the roof of the channel is formed by helices II (residues 29–38) and VI (residues 102–111) of the N- and C-terminal domains, respectively, which run antiparallel to each other; and the floor is formed by the flexible loop (residues 74–82) connecting the two domains and by helix VIII (residues 138–146) of the C-terminal domain. The front of the channel in Figure 7(b) and the left wall of the channel in Figure 7(c) are formed by helices I (residues 7–19) and IV (residues 65–73) and the mini-antiparallel β -sheet comprising residues 26–28 and 62–64, all from the N-terminal domain; the back of the channel in Figure 7(b) and the right wall of the channel in Figure 7(c) are formed by helices V (residues 83–93) and VIII (residues 138–146) and the miniantiparallel β -sheet comprising residues 99–101 and 135–137, all from the C-terminal domain. The two domains of CaM are staggered with a small degree of overlap such that the hydrophobic face of the N-terminal domain mainly contacts the C-terminal half of the M13 peptide, while the C-terminal domain principally interacts with the N-terminal half of M13 (Figure 7(b)).

The overall Ca^{2+} -CaM-M13 complex has a compact globular shape approximating to an ellipsoid with dimensions $4.7 \times 3.2 \times 3.0 \text{ nm}$. The helical M13 peptide passes through the center of the ellipsoid at an angle of about 45° to its

long axis. By way of contrast, the approximate dimensions of the Ca^{2+} -CaM X-ray structure are $6.5 \times 3.0 \times 3.0 \text{ nm}$.⁵² In addition, the calculated radius of gyration for Ca^{2+} -CaM-M13 is about 1.7 nm which is completely consistent with the decrease in the radius of gyration from about 2.1 to about 1.6 nm observed by both small angle X-ray and neutron scattering upon complexation of Ca^{2+} -CaM with M13.⁵⁴

The Ca^{2+} -CaM-M13 complex is stabilized by numerous hydrophobic interactions which are summarized in Figure 8. Particularly striking are the interactions of Trp4 and Phe17 of the peptide which serve to anchor the N- and C-terminal halves of M13 to the C-terminal and N-terminal hydrophobic patches of CaM, respectively [Figure 7(c)]. These interactions also involve a large number of methionine residues which are unusually abundant in CaM, in particular four methionine residues in the C-terminal domain (Met109, Met124, Met144, and Met145) and three methionine residues in the N-terminal domain (Met36, Met51, and Met71). As methionine is an unbranched hydrophobic residue extending over four heavy atoms (C- β , C- γ , S- δ , and C- ϵ), the abundance of methionine residues can generate a hydrophobic surface the detailed topology of which is readily adjusted by minor changes in side-chain conformation, thereby providing a mechanism to accommodate and recognize different bound peptides.⁵⁵

In addition to hydrophobic interactions, there are a number of possible electrostatic interactions that can be deduced from the calculated NMR structures. Putative interactions exist between the Arg and Lys residues of M13 and the Glu residues of CaM, and these are also included in Figure 8. Glu11 and Glu14 in helix I are within 0.5 nm of Lys5 and Lys6 of M13; Glu83, Glu84, and Glu87 in helix V of CaM are close to Lys19, Arg16, and Lys18, respectively, of M13; and Glu127 in helix VII of CaM is close to Arg3 of M13.

The solution structure of the Ca^{2+} -CaM-M13 complex explains a number of interesting observations. Studies of backbone amide exchange behavior have shown that upon complexation with M13, the amide exchange rates of residues 75–79 are substantially increased.⁵⁶ Prior NMR studies on Ca^{2+} -CaM indicated that the long central helix is already disrupted near its middle (from Asp78 to Ser81) in solution⁵⁷ and that large variations in the orientation of one domain relative to the other occur randomly with time.⁵⁸ The further disruption of the central helix upon complexation seen in the structure of the complex is manifested by the increased amide exchange rates, and supports the view of the central helix serving as a flexible linker between the two domains. Similarly, the structure of the complex explains the finding that as many as four residues can be deleted from the middle of the central helix without dramatically altering the stability or shape of the Ca^{2+} -CaM-M13 complex,^{59,60} as the long flexible loop connecting the two domains can readily be shortened without causing any alteration in the structure (see Figure 7). The observation from photoaffinity labeling studies that the two domains of CaM interact simultaneously with opposite ends of the peptide such that residue 4 of the peptide (numbering for M13) can be cross-linked to Met124 or Met144 of the C-terminal domain and that residue 13 of the peptide can be cross linked to Met71 of the N-terminal domain,⁶¹ is readily explained by the structural finding that the N-terminal half of the peptide interacts predominantly with the C-terminal domain, while the C-terminal half of the peptide interacts predominantly with the N-terminal domain (Figures 7 and 8).

Figure 7 Solution structure of the Ca^{2+} -CaM-M13 peptide complex determined by three- and four-dimensional heteronuclear NMR spectroscopy. (a) Superposition of the backbone (N, C α , and C) atoms of 24 simulated annealing structures calculated from the experimental NMR data; the N- and C-terminal domains of calmodulin are shown in blue and red, respectively, and the M13 peptide is in green; the restrained regularized average structure is highlighted. (b, c) Two orthogonal views of a schematic ribbon drawing representation of the structure with the N- and C-terminal domains of CaM in blue and purple, respectively, the M13 peptide in yellow, the hydrophobic side chains of the protein in red, and Trp4, Phe8, Val11, and Phe17 side chains of the peptide in green. The diagrams in (b) and (c) were generated using the program VISP.¹⁰³ The coordinates are from Ikura et al.⁷ (PDB accession code 1BBM). (Adapted from M. Ikura, G. M. Clore, A. M. Gronenborn, G. Zhu, C. B. Klee, and A. Bax, *Science*, 1992, **256**, 632)

Figure 8 Summary of residue pairs for which intermolecular NOEs between CaM and M13 are observed. CaM residues involved in hydrophobic interactions are boxed. Also included are potential electrostatic interactions between negatively charged Glu residues of CaM (shown in parentheses) and positively charged Lys and Arg residues of M13. (Adapted from M. Ikura, G. M. Clore, A. M. Gronenborn, G. Zhu, C. B. Klee, and A. Bax, *Science*, 1992, **256**, 632)

The observation that at least 17 residues of the M13 peptide from either skeletal muscle or smooth muscle are necessary for high affinity binding^{62,63} is readily explained by the intimate interactions of the C-terminal hydrophobic residue (i.e. Phe17) with the N-terminal domain of CaM by which the peptide is anchored. Finally, the structure accounts for experiments in which cross-linking of residues 3 and 146 of CaM, mutated to Cys, has no effect on the activation of myosin light chain kinase, even if the central helix is cleaved proteolytically at Lys77 by trypsin.⁶⁴ Thus, while the atoms of the residues 3 and 146 are 3.7 nm apart in the X-ray structure of Ca^{2+} -CaM, they are only about 2.0 nm apart in the solution structure of

the Ca^{2+} -CaM-M13 complex, which is close enough to permit cross-linking to occur.

A large body of experimental data shows that CaM binds to numerous proteins whose binding domains exhibit a propensity for α -helix formation.⁵¹ A comparison of these sequences reveals little homology. Nevertheless, many of the very tightly binding peptides ($K_{\text{ass}} \geq 5 \times 10^7 \text{ M}^{-1}$) have the common property of containing either aromatic residues or long-chain hydrophobic residues (Leu, Ile, or Val) separated by 12 residues, as summarized in Figure 9. In the case of M13, these two residues are Trp4 and Phe17 which are exclusively in contact with the C- and N-terminal domains, respectively.

[illegible]

Figure 9 Alignment of tightly binding ($K_{\text{ass}} \geq 5 \times 10^7 \text{ M}^{-1}$) CaM binding sequences based on the structural role of Trp4 and Phe17 in anchoring the M13 peptide to the C- and N-terminal domains, respectively, of CaM. (Adapted from M. Ikura, G. M. Clore, A. M. Gronenborn, G. Zhu, C. B. Klee, and A. Bax, *Science*, 1992, **256**, 632)

of CaM, (Figure 7 and Figure 8). Given that these two residues are involved in more hydrophobic interactions with CaM than any other residues of the peptide (see Figure 8), it seems likely that this feature of the sequence can be used to align the CaM binding sequences listed in Figure 9, thereby permitting one to predict their interaction with CaM. It is clear from this alignment that the pattern of hydrophobic and hydrophilic residues is, in general, comparable for the various peptides, suggesting that the mode of binding and the structure of the corresponding complexes with Ca^{2+} -CaM are also likely to be similar. For example, there is, in general, conservation of hydrophobic residues at the positions equivalent to Phe8 which interacts with the C-terminal domain and Val11 which interacts with both domains (see Figures 7 and 8). In addition, there are no acidic residues present which would result in unfavorable electrostatic interactions with the negatively charged Glu residues on the surface of CaM (see Figure 7). The minimum length of peptide required for high affinity binding to Ca^{2+} -CaM is defined by the 14 residue mastaporans which comprise the two hydrophobic residues at the N- and C-termini (Figure 9) and have approximately the same equilibrium association constant ($K_{\text{ass}} \approx 1-3 \times 10^9 \text{ M}^{-1}$) as M13.⁶⁵ This structural alignment also predicts that a peptide stopping just short of the second hydrophobic residue of the pair (i.e. the residue equivalent to Phe17) would only bind to the C-terminal domain and that the resulting complex would therefore retain the dumb-bell shape of Ca^{2+} -CaM. This is exactly what has been observed by small angle X-ray scattering using two synthetic peptides, C24 W and C20 W (Figure 9), comprising different portions of the CaM binding domain of the plasma membrane Ca^{2+} pump.⁶⁶ The complex with the C24 W peptide which corresponds to residues 1–24 of M13 and contains a Trp at position 4 and a Val at position 17, has a globular shape similar to that of Ca^{2+} -CaM–M13. The complex with the C20 W peptide, on the other hand, which corresponds to residues –4 to 16 of M13 and therefore lacks the C-terminal hydrophobic residue of the pair, retains the dumb-bell shape of Ca^{2+} -CaM, suggesting that the peptide only binds to the C-terminal domain.

Thus the solution structure of the complex of Ca^{2+} -CaM with M13 reveals an unusual binding mode in which the target peptide is sequestered into a hydrophobic channel formed by the two domains of CaM with interactions involving 19 residues of the target peptide (i.e. residues 3–21 of M13). In addition, a key requirement appears to be the presence of two long-chain hydrophobic or aromatic residues separated by 12 residues in order to anchor the peptide to the two domains of CaM (Figure 7). By analogy, the rope (i.e. the CaM binding domain of the target) has to be long enough and have two knots at each end for the two hands (i.e. domains) of CaM to grip it. This particular mode of binding is therefore only likely to occur if the CaM binding site is located either at an easily accessible C- or N-terminus or in a long exposed surface loop of the target protein. An example of the former is myosin light chain kinase and of the latter is calcineurin, and, in accordance with their location, the CaM binding sites are susceptible to proteolysis.^{63,67} Clearly, other types of complex between Ca^{2+} -CaM and its target proteins are possible, given the inherent flexibility of the central helix. For example, in the case of the γ -subunit of phosphorylase kinase, it appears that there are two discontinuous CaM binding sites which are capable of binding to Ca^{2+} -CaM simultaneously,⁶⁸ and

binding of a peptide derived from one of these sites causes elongation rather than contraction of Ca^{2+} -CaM,⁶⁹ indicating that the complex is of a quite different structural nature. Similarly, in the case of cyclic nucleotide phosphodiesterase⁷⁰ and CaM kinase II,⁷¹ the CaM binding sequences do not have the same spacing of hydrophobic residues seen in M13 and the other sequences listed in Figure 13 (see below) and, in addition, CaM kinase II is not susceptible to proteolysis in the absence of phosphorylation,⁷² suggesting that the mode of binding is different again. Thus, in all likelihood, the complexes of Ca^{2+} -CaM with target peptides from skeletal and smooth muscle myosin light chain kinase represent one of a range of Ca^{2+} -CaM binding modes achieving CaM–target protein interactions in an efficient and elegant manner.

5.2 The Structure of the Specific Complex of the Transcription Factor GATA-1 with DNA

The erythroid specific transcription factor GATA-1 is responsible for the regulation of transcription of erythroid-expressed genes and is an essential component required for the generation of the erythroid lineage.⁷³ GATA-1 binds specifically as a monomer to the asymmetric consensus target sequence (T/A)GATA(A/G) found in the *cis*-regulatory elements of all globin genes and most other erythroid specific genes that have been examined.⁷⁴ GATA-1 was the first member of a family of proteins, which now includes regulatory proteins expressed in other cell lineages, characterized by their recognition of the GATA DNA sequence and by the presence of two metal binding regions of the form Cys-X-X-Cys-(X)₁₇-Cys-X-X-Cys separated by 29 residues. Mutation and deletion studies on GATA-1 have indicated that the N-terminal metal binding region is not required for specific DNA binding,⁷⁵ and studies with synthetic peptides have demonstrated conclusively that a 59 residue fragment (residues 158–216 of chicken GATA-1) comprising the C-terminal metal binding region complexed to zinc and 28 residues C-terminal to the last Cys constitutes the minimal unit required for specific binding ($K_{\text{ass}} \approx 1.2 \times 10^8 \text{ M}^{-1}$).⁷⁶ In order to understand the mechanism of specific DNA recognition by GATA-1 we set out to solve the solution structure of the specific complex of a 66 residue fragment (residues 158–223) comprising the DNA binding domain of chicken GATA-1 (cGATA-1) with a 16 base pair oligonucleotide containing the target sequence AGATAA, by means of multidimensional heteronuclear filtered and separated NMR spectroscopy.⁸

The structure calculations were based on a total of 1772 experimental NMR restraints, including 117 intermolecular interproton distance restraints between the protein and the DNA. A stereoview of a best-fit superposition of 30 calculated structures (residues 2–59 of the protein and base pairs 6 to 13 of the DNA) is shown in Figure 10. The N-terminus (residue 1) and C-terminus (residues 60–66) of the protein are disordered. Base pairs 6 to 13 of the DNA are in contact with the cGATA-1 DNA binding domain and are well defined both locally and globally. The orientation, however, of the first five and last three base pairs of the DNA, which are not in contact with the protein, is poorly defined with respect to the core of the complex, although the conformation of each of these bases at a local level is reasonably well defined. This is due to the fact that, in addition to their approximate

Figure 10 Stereoview showing a superposition of the 30 simulated annealing structures of the specific complex of the DNA binding domain of cGATA-1 with DNA calculated on the basis of the experimental NMR data derived from three- and four-dimensional heteronuclear NMR spectroscopy. The backbone (N, C α , and C) atoms of cGATA-1 are shown in red and all the non-hydrogen atoms of the DNA in blue. The restrained regularized mean structure of the complex is highlighted. The coordinates are from Omichinski et al.⁸ (PDB accession code 1GAT). (Adapted from J. G. Omichinski, G. M. Clore, O. Schaad, G. Felsenfeld, C. Trainor, E. Appella, S. J. Stahl, and A. M. Gronenborn, *Science*, 1993, **261**, 438)

nature, the interproton distance restraints within the DNA are solely sequential. Hence, they are inadequate to ascertain the relative orientation of base pairs separated by more than 5–6 steps with any great degree of precision and accuracy. The global conformation of the central eight base pairs, on the other hand, is determined not only by the restraints within the DNA, but more importantly by the large number of intermolecular interproton distance restraints between the protein and DNA. The atomic rms distribution of the 30 SA structures about the mean coordinate positions for the complex proper (i.e. residues 2–59 of the protein and base pairs 6–13 of the DNA) is 0.070 ± 0.013 and 0.113 ± 0.008 nm for protein backbone plus DNA and all protein atoms plus DNA, respectively.

The protein can be divided into two modules: the protein core which consists of residues 2–51 and contains the zinc coordination site, and an extended C-terminal tail (residues 52–59).

A schematic ribbon drawing of the core is presented in Figure 11(a). The core starts out with a turn (residues 2–5), followed by two short irregular antiparallel β -sheets, a helix (residues 28–38) and a long loop (residues 39–51) which includes a helical turn (residues 44–47), as well as an Ω like loop (residues 47–51). β -strands 1 (residues 5–7) and 2 (residues 11–14) form the first β -sheet, while β -strands 3 (residues 18–21) and 4 (residues 24–27) form the second β -sheet.

Part of the core of the cGATA-1 DNA binding domain is structurally similar to that of the N-terminal zinc containing module of the DNA binding domain of the glucocorticoid receptor.⁷⁷ Thus the C α atoms of 30 residues of these two proteins can be superimposed with an rms difference of only 0.14 nm Figure 11(b). Apart from the four Cys residues that coordinate the zinc atom, only 1 residue (Lys36 in the cGATA-1 DNA binding domain and Lys465 in the glucocorticoid receptor) is conserved between the two proteins. The structural similarity extends from the N-terminus up to the end of the helix (residues 3–39 of the cGATA-1 DNA binding domain and residues 436 to 468 of the glucocorticoid receptor), and

the Zn–S γ geometry, as well as the side-chain conformations of the four coordinating cysteines, are identical. The loop between strands β 2 and β 3 has three deletions, and the turn between strands β 3 and β 4 has one deletion in the glucocorticoid receptor with respect to cGATA-1. The topology and polypeptide trace following the carboxyl end of the helix, however, are entirely different in the two proteins. Thus, in the DNA binding domain of the glucocorticoid receptor there is a second compact zinc containing module (residues 470–514) made up of two strands and two helices, while in the cGATA-1 DNA binding domain there is a long loop (residues 38–51) and extended strand (residues 52–59).

The overall topology and structural organization of the complex is shown in Figures 12(a) and 12(b). The conformation of the oligonucleotide is of B type. The helix and the loop connecting strands β 2 and β 3 (which is located directly beneath the helix) are located in the major groove, while the C-terminal tail wraps around the DNA and lies in the minor groove, directly opposite the helix. The overall appearance is analogous to that of a right hand holding a rope, with the rope representing the DNA, the palm and fingers of the hand the core of the protein, and the thumb the C-terminal tail. It is this pincer-like configuration of the protein that causes a small 10° kink in the DNA. The long axis of the helix lies at an angle of about 40° to the base planes of the DNA [Figure 12(a)], while the C-terminal tail is approximately parallel to the base planes [Figure 12(b)].

Views of side-chain contacts with the DNA in the major and minor grooves are shown in Figures 12(c) and 12(d), respectively, while a schematic representation of all the contacts is provided in Figure 13. The cGATA-1 DNA binding domain makes specific contacts with eight bases, seven in the major groove (A6, G7, A8, T25, A24, T23, and T22) and one in the minor groove (T9). All the base contacts in the major groove involve the helix and the loop connecting β -strands 2 and 3. In contrast to other DNA binding proteins, the majority of base contacts involve hydrophobic interactions. Thus, Leu17 interacts with A6, G7, and T25; Thr16 with A24 and T25; Leu33 with A24 and T23; and Leu37 with T23 and T22. This accounts for the predominance of thymidines in the DNA target site. Indeed, there are only three hydrogen-bonding interactions: namely, between the side chain of Asn29 and the N-6 atoms of A24 and A8 in the major groove, and between the N ζ H $_3^+$ of Lys57 and the O-2 atom of T9 in the minor groove. In this regard, it is interesting to note that there is a reduction of 11.27 nm² in the surface accessible area of the cGATA-1 DNA binding domain in the presence of DNA (corresponding to a 20% decrease in the accessible surface), and a decrease in the calculated solvation free energy of folding⁵³ of 13 kcal mol⁻¹ (54 kJ mol⁻¹). This latter effect can clearly make a sizable contribution to the specific binding constant ($K_{\text{ass}} \approx 1.2 \times 10^8$ M⁻¹).

The remaining contacts involve the sugar–phosphate backbone, the majority of which are located on the second strand (that is G20 to T27). Salt bridges and/or hydrogen bonds with the phosphates of G7, A24, and T22 are made by Arg19, Arg47, and His38, respectively, in the major groove, and with the phosphates of C13, T25, C26 and T27 by Arg54, Thr53, Arg56, and Ser59, respectively, in the minor groove. The interactions of Arg54, and Arg56 above and below the polypeptide chain span the full length of the target site and are probably responsible for the bending of the DNA in the direction of the

Figure 11 (a) Schematic ribbon drawing of the core of the cGATA-1 DNA binding domain. (b) Superposition of the C α atoms of the cGATA-1 (green) and glucocorticoid receptor (red) DNA binding domains. The zinc and coordinating cysteines are shown in yellow for cGATA-1 and in purple for the glucocorticoid receptor; the residues are labeled according to the numbering in cGATA-1. The alignment of cGATA-1 with the glucocorticoid receptor is as follows: residues 3–13, 18–21, 25–39, and 46 of cGATA-1 are superimposed on residues 436–446, 448–451, 454–468, and 490, respectively, of the glucocorticoid receptor with a C α atomic rms of 0.14 nm. The diagram in (a) was made using the program MOLSCRIPT.¹⁰² The coordinates of the glucocorticoid receptor DNA binding domain shown in (b) are taken from Luisi et al.⁷⁹ The cGATA-1 coordinates are from Omichinski et al.⁸ (PDB accession code 1GAT). (Adapted from J. G. Omichinski, G. M. Clore, O. Schaad, G. Felsenfeld, C. Trainor, E. Appella, S.J. Stahl, and A. M. Gronenborn, *Science*, 1993, **261**, 438)

minor groove. Likewise, all the sugar contacts involve the second strand. In the major groove they are hydrophobic in nature, and involve contacts between the sugars of T22, T23 and A24 with Tyr34, Leu33 and Ala30, and Ile51 and Thr16, respectively. In the minor groove, hydrophobic sugar DNA–protein interactions are made by C-13 with the aliphatic portion of the side chain of Arg54, T23 and T24 with Gln52, T25 and C26 with the aliphatic portion of the side chain of Arg 56, and C26 with Ser59. In addition, there is a hydrogen bond between the side-chain amide of Gln52 and the sugar O-3' atom of T23.

The mode of specific DNA binding protein that is revealed in this structure is distinct from that observed for the other three classes of zinc containing DNA binding domains whose structures have previously been solved.^{77–82} Features specific to the complex with the DNA binding domain of cGATA-1 include: the relatively small size of the DNA target site (eight base pairs of which only a contiguous stretch of six is involved in specific contacts); the monomeric nature of the complex in which only a single zinc binding module is required for specific binding; the predominance of hydrophobic interactions involved in specific base contacts in the major groove; the presence of a basic C-terminal tail which interacts with the DNA in the minor groove and constitutes a key component of specificity; and, finally, the pincer-like nature

of the complex in which the core and tail subdomains are opposed and surround the DNA just like a hand gripping a rope. The structure of the cGATA-1 DNA binding domain reveals a modular design. The fold of residues 3–39 is similar to that of the N-terminal zinc binding module of the DNA binding domain of the glucocorticoid receptor, although, with the exception of the four Cys residues that coordinate zinc, there is no significant sequence identity between these regions of the two proteins. Residues 40–66 are part of a separate structural motif. In this regard it is interesting to note that, in addition to both zinc binding modules being encoded on separate exons in the cGATA-1 gene (exons 4 and 5), the next intron/exon boundary lies between amino acids 39 and 40 (current numbering scheme) of the DNA binding domain, thereby separating the C-terminal zinc binding domain from the basic tail⁸³.

5.3 Hydration of the Specific Complex of the Transcription Factor GATA-1 with DNA

A number of recent high resolution crystal structures of protein–DNA complexes have suggested that bound water may play an important role in the recognition process in the

Figure 12 (a, b) Schematic ribbon drawings illustrating the interactions of cGATA-1 with DNA. (c, d) Side-chain interactions between cGATA-1 and the DNA in the major and minor grooves, respectively. The protein backbone is shown in green and the protein side chains in yellow; the color code for the DNA bases is as follows: red for A, lilac for T, dark blue for G, and light blue for C. The diagrams were made using the program VISP.¹⁰³ The coordinates of the cGATA-1–DNA complex are from Omichinski et al.⁸ (PDB accession code 1GAT). (Adapted from J. G. Omichinski, G. M. Clore, O. Schaad, G. Felsenfeld, C. Trainor, E. Appella, S. J. Stahl, and A. M. Gronenborn, *Science*, 1993, **261**, 438)

form of indirect read-out in which the bound water molecules serve to bridge hydrogen bonds between functional groups on the protein and the DNA bases.^{84–86} In addition, a bound water molecule has been detected at the interface of the complex between the *Antp*(C39 S) homeodomain and a 14-base pair duplex in solution using NMR spectroscopy.⁸⁷ In contrast to other protein–DNA complexes, in which the majority of specific interactions involve hydrogen bonds between the protein and the DNA bases, the structure of the specific complex of GATA-1 with DNA, as indicated in the previous section, suggests that hydrophobic effects constitute a large proportion of the specific binding energy.⁸ This would predict that water of hydration would be excluded from the interface between GATA-1 and the DNA bases in the major groove, but would be present at the interface between GATA-1 and the

sugar–phosphate backbone, as well as at the solvent exposed surface of the protein. To test this hypothesis we carried out selective two-dimensional H₂O NOE and H₂O rotating frame Overhauser effect (ROE) ¹H–¹⁵N and ¹H–¹³C heteronuclear single quantum correlation experiments⁸⁸ to detect through space (<0.4 nm) contacts between bound water and protons of the protein, thereby identifying the location of bound water molecules in the specific complex of chicken GATA-1 with DNA.⁸⁹

A number of water molecules could be detected between the protein and the phosphate backbone, as well as at the solvent exposed surface of the protein. However, no water molecules could be observed at the interface of the protein with the bases of the DNA. With only one exception, the bound water molecules have a residency time greater than 200–300 ps. On

Figure 13 Schematic diagram summarizing the contacts between cGATA-1 and DNA. The DNA is represented as a cylindrical projection. Bases interacting with the protein are shaded; phosphates are represented as circles; circles with hatches directed towards the right and left indicate sites of interaction with sugar or phosphate or both in the major and minor grooves, respectively. (Adapted from J. G. Omichinski, G. M. Clore, O. Schaad, G. Felsenfeld, C. Trainor, E. Appella, S. J. Stahl, and A. M. Gronenborn, *Science*, 1993, **261**, 438)

the basis of the structure of the complex of GATA-1 with DNA,⁸ we were able to identify unambiguously 17 methyl protons and 3 backbone NH protons in close proximity to bound water.⁸⁹ The location of the protein residues near bound water are indicated in the structure of the complex of GATA-1 with DNA shown in Figure 14.

An approximate estimate of the residency times of these bound water molecules can be obtained from the sign of the NOE.^{9,90} If a water molecule is bound to a macromolecule with a correlation time in the spin diffusion limit (i.e. greater than about 2 ns), the NOE between water and a protein proton will be zero for a residency time of about 300 ps, while for residency times smaller and longer than 300 ps the NOE will be positive and negative, respectively. In contrast, the ROE remains positive for all residency and correlation times. The NH protons of Ala30, Tyr34, and Tyr35 and the methyl groups of Ala3, Ala30, Met46, and Ile51 (γ_m and δ_m) exhibited negative NOEs to water, indicating a residency time greater than about 500 ps. The methyl protons of Met23 exhibited a positive NOE to water, indicative of a residency time of 100–300 ps. For the remaining surface methyl protons, the NOEs (at a mixing time of 60 ms) to water were too weak to

observe and only ROEs were seen, indicating residency times in the range 200–500 ps.

All methyl groups that are exposed to solvent are associated with bound water molecules. These include Ala3, Val6 (γ_1 and γ_2), Leu17 (δ_2 only), Met23, Val40 (γ_1 and γ_2), Leu44 (δ_1 and δ_2), and Val58 (γ_1 and γ_2). Bound water molecules in contact with exposed hydrophobic surfaces are rarely seen in protein crystal structures as the water molecules are only well ordered (high occupancy and low thermal factor) if the protein donates anchor points in suitable hydrogen-bonding positions.⁹¹ In the absence of hydrogen bonding, low occupancies and high thermal B factors render such water molecules unobservable.⁹¹ Indeed, there is only one crystallographic example where water surrounding an exposed hydrophobic group has been seen in the absence of hydrogen bonding, namely the water pentagons surrounding Leu18 in the 0.088 nm resolution crystal structure of crambin.⁹² In contrast to the crystallographic case, bound water can be readily detected by NMR over a very wide range of residency times (with a lower limit of 50–100 ps) and is not eliminated by rapid independent rotation of a water pentagon around a rotating methyl group. Moreover, the NMR experiment is not dependent on uniform ordering insofar as the bound water could be in somewhat different positions

Figure 14 Stereoview of the solution structure of the specific complex of GATA-1 and DNA, illustrating the location of groups in close proximity to bound water. The DNA is displayed in blue, the protein backbone in red, and the side chains in close proximity to bound water detected in the H_2O ROE/NOE HSQC (heteronuclear single quantum correlation) experiments in green. The side chain of Leu33 which interacts directly with the bases of the DNA in the major groove and is not close to bound water is shown in orange. In the case of Leu17, only the surface exposed $\text{C}^{\delta 2}\text{H}_3$ methyl group gives rise to a ROE with bound water; the $\text{C}^{\delta 1}\text{H}_3$ methyl group which interacts directly with the DNA bases is not close to bound water. The model is taken from the solution NMR structure given by Omichinski et al.⁸ (PDB accession number 1GAT) and was generated using the program VISIP.¹⁰³ (Adapted from G. M. Clore, A. Bax, J. G. Omichinski, and A. M. Gronenborn, *Structure*, 1994, 2, 89)

in different molecules. In the X-ray diffraction experiment, on the other hand, bound water could only be detected if it occupied the same position in different protein molecules; that is to say there has to be uniform ordering of the bound water throughout the protein molecules of the crystal. Consequently, rapid rotation of a water pentagon about a methyl group, in the absence of discrete hopping, would result in smearing of the electron density beyond the limit of detectability.

The ubiquitous presence of bound water molecules close to exposed hydrophobic groups observed by NMR is completely consistent with the thermodynamic results of Privalov and Makhatadze,^{93,94} who showed that the hydration of methyl groups is associated with a large negative entropy ($-40.3 \text{ J mol}^{-1} \text{ K}^{-1}$), a negative enthalpy ($-8.28 \text{ kJ mol}^{-1}$) and only a small positive Gibbs free energy (3.72 kJ mol^{-1}). Indeed, the entropy of hydration of methyl groups is comparable to that of polar groups (-41 to $-50 \text{ J mol}^{-1} \text{ K}^{-1}$), indicating that their ordering power for water is comparable.

All methyl groups that are in close proximity to the phosphodiester backbone but do not interact with the bases are also associated with bound water molecules. In these cases, it is clear that the water is stabilized by hydrogen bonding interactions with either the phosphate group or the O-5' and O-3' oxygen atoms. Interestingly, similarly located water molecules have also been observed in crystal structures of DNA–protein complexes.^{95,96} The results on the specific complex of GATA-1 with DNA indicate the presence of a cluster of water molecules in the vicinity of the sugar–phosphate backbone of T22, T23, A24, and T25. It is important to note, however, that these interactions do not confer specificity. In the minor groove there is a bound water molecule(s) between the $\text{C}^{\epsilon}\text{H}_3$ of Met46, the sugar of T22 and the phosphate of T23. In the major groove, four clusters of bound water molecules are observed: namely between the $\text{C}^{\delta 2}\text{H}_3$ methyl group of Leu37 and the sugar and phosphate of T22; between the $\text{C}^{\delta 1}\text{H}_3$ of Leu37, the backbone NH protons

of Tyr34 and Tyr35, and the phosphate of T23; between the methyl group of Ala30, the NH proton of Ala30, and the phosphate of A24; and finally between the $\text{C}^{\gamma}\text{H}_3$ and $\text{C}^{\delta}\text{H}_3$ methyl groups of Ile51, the sugar of A24 and the phosphate of T25. In all likelihood, the water molecule(s) associated with the NH protons Tyr34 and Tyr35, and with the NH proton of Ala30, participate in bridging hydrogen bonds between the relevant amide group of the protein and the sugar–phosphate backbone of the DNA.

In contrast to the above methyl groups, no NOEs or ROEs to water were observed for either of the two Leu33 methyl groups or the $\text{C}^{\delta 1}\text{H}_3$ methyl group of Leu17, all of which are involved in hydrophobic interactions with the bases.⁸ This indicates that water is excluded from the interface between the protein and the DNA bases in the major groove. In addition, complementary conventional two-dimensional ^1H – ^1H NOE experiments with ^{12}C filtering failed to detect any bound water close to the thymine methyl groups of the DNA, providing further evidence for the exclusion of water at the interface of the protein and the DNA bases. The absence of water at the interface between the protein and the DNA bases in the major groove lends further credence to the importance of hydrophobic interactions in stabilizing the specific interaction between chicken GATA-1 and DNA, and indicates that hydrophobic interactions can play an important role in protein–DNA recognition and specificity.

6 CONCLUDING REMARKS

From the examples presented in this article it should be clear that the recent development of a whole range of highly sensitive multidimensional heteronuclear edited and filtered NMR experiments has revolutionized the field of protein structure determination by NMR. Proteins and protein–ligand complexes in the 15–25 kDa range are now amenable to detailed

structure analysis in solution. Moreover, the potential of the current methods can probably be extended to systems even up to 40 kDa, providing that they are very well behaved from an NMR perspective. Nevertheless, despite these advances, it should always be borne in mind that there are a number of key requirements that have to be satisfied to permit a successful structure determination of larger proteins and protein complexes by NMR. The protein in hand must be soluble and should not aggregate up to concentrations of about 1 mM, it must be stable at room temperature or slightly higher for many weeks, it should not exhibit significant conformational heterogeneity that could result in extensive line broadening, and finally it must be amenable to uniform ^{15}N and ^{13}C labeling. At the present time there are only a few examples in the literature of proteins in the 15–25 kDa range that have been solved by means of multidimensional heteronuclear NMR spectroscopy. In addition to the three examples presented here, only the structures of interleukin-4,^{33,97,98} glucose permease IIA,⁹⁹ the complex of cyclophilin with cyclosporin,¹⁰⁰ and the *Antennapedia* homeodomain-DNA complex¹⁰¹ have been published. It is hoped that over the next few years, the widespread use of these multidimensional heteronuclear experiments coupled with semiautomated assignment procedures will result in many more NMR structures of such larger proteins and protein-ligand complexes.

1 INTRODUCTION

Over many years we have been involved with the synthesis and characterization of peptides as biologically active agents. The goal of this research has been to develop structure and biological function relationships. The structure–activity relationships are then used in the rational design of new molecules with greater activity, enhanced duration of action, and/or increased selectivity. The number of peptides with interesting biological activity has been rising rapidly. These peptides possess a wide range of biological activities acting as antibiotics, enzyme inhibitors, taste ligands, hormones, immunosuppressants, neurotransmitters, and neuromodulators.

We have undertaken a multifaceted program including synthesis and spectroscopic characterization, with NMR the most important, coupled with various computational techniques. In this article we shall focus our attention on the use of NMR in the conformational analysis of synthetic peptides. However, it is important to note the significant roles of the other components of our approach within this field of study. In no way is this article intended to be an all-inclusive review of the examination of synthetic peptides by NMR, an undertaking which would all too soon be out of date and would require a complete volume on its own. In contrast, we will concentrate on a few important points within the field, using examples mainly taken from our own research.

2 CONFORMATION OF PEPTIDES

The inherent flexibility of peptides remains one of the biggest obstacles in their conformational study. Before one can hope to understand the relationship between structure and activity, the molecule under study must have predominant conformations. Usually, a linear peptide in solution has too many degrees of freedom, and can adopt an overwhelmingly large number of conformations. Because of their small size, synthetic peptides do not possess a hydrophobic core, which

helps stabilize many of the secondary elements, α -helices or β -sheets, often found in proteins. As a result, the surface area of a peptide is extremely large. This greatly increases the influence of the environment or solvent on the conformation of a peptide, as well as on its dynamics and molecular motions.

To reduce the number of accessible conformations and to induce preferred conformations, molecular constraints are introduced by synthetic chemists. The challenge is to introduce constraints into the molecule, while at the same time maintaining the favorable biological properties. We therefore begin with a brief overview of the most important tools in the synthetic peptide chemists' arsenal to prepare constrained molecules. We then address some of the specific concerns in the computational refinement of peptide structures using NMR data. Finally, we discuss important aspects of the NMR investigation of synthetic peptides.

3 SYNTHETIC METHODS

Cyclized structures represent the most important approach to introduce conformational constraints. Cyclization can most obviously be achieved by the formation of a covalent bond between the N-amino terminal and C-carboxyl terminal moieties of the peptide. In many cases, including somatostatin and thymopoietin, such structures have led to active analogs while reducing the number of possible conformations. However, in many cases this approach destroys biological activity.

Another route to cyclic structures involves side-chain bonding. The side chain of the amino terminus of lysine (Lys) or carboxyl terminus of glutamic acid (Glu) and aspartic acid, can be covalently connected to each other or to either the N or C backbone termini.¹ The formation of a lactam bridge greatly reduces the number of conformations. The number of methylene groups within the side-chain linkers can be reduced by using ornithine, α,γ -diaminobutyric acid, or α,β -diaminopropionic acid in place of the Lys.

Side-chain cyclization can also be accomplished by using the disulfide bond of cysteine (Cys). This method has been incorporated in a number of important peptide-producing systems. To reduce the flexibility even further penicillamine (β,β -dimethylated-cysteine) can be used in place of Cys.

A new approach in cyclization has recently been reported in which the nitrogen atom of a backbone amide is alkylated and terminated with an acid or amino group.² This reacting group can then be connected to one of the termini (backbone–C-terminal cyclization, or backbone–N-terminal cyclization) or to another linker extending from the backbone of another residue within the sequence.

The naturally occurring proline (Pro) residue can be considered as a constraining residue. The five-membered ring greatly reduces the possible conformations about the ϕ -dihedral angle. However, Pro also often introduces complications into the NMR spectra because of *cis/trans* isomerization. This can complicate the spectra of small peptides. The opioid morphiceptin, Tyr-Pro-Phe-Pro-NH₂ (where Tyr = tyrosine, Phe = phenylalanine) shows a complex NMR spectrum. *cis/trans* isomerization can arise between the Tyr-Pro and Phe-Pro residues. All four different possible configurational isomers (*trans–trans*, *cis–trans*, *trans–cis*, and *cis–cis*) were observed in the ¹H and ¹³C spectra.³ To simplify the spectra, the Pro was substituted by a peptidomimetic residue,

Figure 1 Structural formulae of (a) Pro and (b) 2-aminocyclopentanoic acid. The dihedral angle about the peptide bond, ω , is indicated

2-aminocyclopentanoic acid, which maintains a similar conformational constraint of Pro while not allowing for the *cis/trans* isomerization.⁴ The amide group in the mimetic residue is a secondary amine which removes the possibility of *cis/trans* isomerization (Figure 1).

The control of the orientation of side chains has recently become a major focus of research interest. The approach usually involves the attachment of additional groups to the beta positions of the side chains. One or both of the beta protons can be replaced with methyl groups or a covalent linkage between the backbone and the side chain introduced to maintain preferred orientations.

4 COMPUTER SIMULATIONS

There are some specific concerns in the computational refinement of peptide structures from NMR data. There are far fewer NOEs than typically found for proteins on an NOE per residue basis. However, because of the better resolution of the cross peaks from NOESY spectra, the distances deduced for peptides can be considered to be more accurate. This comes from the fact that the intensity of the cross peaks can be integrated which must be contrasted with the grouping of NOEs into strong, medium, and weak categories, the method used in the NMR examination of larger biomolecules. The intensities are then converted into a range of distances using the cross-peak intensity of a reference pair of protons of known distance (isolated two-spin approximation). This method assumes that each proton–proton vector has the same correlation time, an assumption which, from molecular dynamics simulations, introduces about a 10% error.⁵ Therefore the upper and lower distance restraints should be adjusted by plus and minus 10%, respectively. Often in addition to the cross peaks, the diagonal peaks can be integrated and the ratio of the intensities can be used to generate distances.⁶ In a recent examination of a small synthetic molecule, both of these approaches were compared and found to produce very similar distances.⁷

Although the calculation of the distances may be rather straightforward with peptides, it is important that flexibility is always kept in mind. In the presence of conformational averaging, fast on the NMR timescale, the measured NOEs represent an average structure that may not exist in solution or even be physically possible. The distances generated from the NOEs are weighted as a function of the inverse sixth power of the different conformations so that small distances contribute heavily to the average. Although this is true for all systems studied by NMR, it is especially problematic for peptides because of their inherent flexibility.

Computational procedures which utilize average experimental restraints, rather than instantaneous restraints, have been

developed for situations of conformational averaging. The method can be simply illustrated by the following penalty function:

$$\text{Penalty} = \frac{1}{2}K(\text{experimental} - \langle \text{calculated} \rangle)^2 \quad (1)$$

where K is a force constant to weight the significance of the penalty with respect to the other terms used in the refinement calculation. The value of the observable (i.e. NOE, coupling constant, chemical shift) is averaged, denoted by the angle brackets, before it is compared with the experimentally measured value. If the average value is removed from the experimental value the penalty function is applied.

One method used in molecular dynamics simulations calculates the observable over a specific time period before application of the restraint.⁸ If the average value calculated over this time span is removed from the experimental value, the penalty function is applied. This method of time-dependent restraints was first used for NOEs and has recently been applied to coupling constant restraints.⁹

Another approach to applying experimental restraints for systems undergoing conformational averaging uses an ensemble of structures.¹⁰ The ensemble approach utilizes a large number of structures, an ensemble, rather than the single structure used in standard refinement calculations. For NOEs, the average distance is calculated from the ensemble, properly weighted to the inverse sixth power, and if removed from the experimental value, the penalty function applied to the ensemble. The ensemble method has recently been modified to include coupling constant restraints.¹¹

Of course, both the time-dependent and the ensemble procedures should produce the same answer. In practice, small differences have been noted, but these can be attributed to the different methods of calculation employed.¹² Nevertheless, it is clear that since the experimental observables (i.e. NOEs, coupling constants) are average quantities, the restraints must also be applied as such in the refinement calculations.

One important aspect in the computational refinement of the structure of synthetic peptides derives from their small size which allows for a more thorough and systematic conformational search. Procedures for systematic searching have been shown to be quite useful. Although all of the possible conformations cannot usually be examined, many approximate methods can be used. As an example, for each low-energy backbone conformation found, all of the possible side-chain orientations are examined. With the approximation that the side chains adopt only the three staggered rotamers, -60° , 180° , and 60° , the number of conformations to examine becomes quite manageable.¹³ Distance geometry methods can be employed to study many different starting structures. Although distance geometry has historically been used for systems with a large number of loosely defined restraints, some new methods, namely random metrization,¹⁴ have been introduced which should help in the examination of peptides, where the number of NOEs is limited.

One last point in the refinement of peptide structures is consideration of the environment (i.e. inclusion of the solvent explicitly or a computational method to mimic the solvent). The large surface area of the peptide means that solvent plays a significant role in conformational preferences and molecular dynamics. It is therefore important that the environment be simulated during the calculations. In recent years, progress in this area has been reported. Many of the

organic solvents commonly used in the NMR investigations of synthetic peptides are available for computer simulations.^{15,16}

5 NMR INVESTIGATIONS OF SYNTHETIC PEPTIDES

The NMR examination of synthetic peptides is quite unique, when compared with other biomolecules. There are many problems which are not present in the study of proteins or nucleic acids. The typical size of the molecules renders the NOESY experiment, which provides the most conformationally relevant information, very inefficient. In addition, the lack of secondary structure and therefore inherent flexibility of peptides, which we have touched upon above, alters the general approach of the NMR investigation.

5.1 ROESY Experiments

The most important development in the NMR field for the study of the structure of peptides has to be the idea of the NOE within the rotating frame, first called CAMELSPIN,¹⁷ now more commonly referred to as ROESY.¹⁸ Most synthetic peptides have a motional correlation time, τ_c , which at the high fields standardly used today (400–600 MHz), produces the condition of $\omega\tau_c = 1$ (where ω is the Larmor frequency), a condition in which the intensity of the NOE approaches zero. In simple terms, the buildup of the NOE is governed by the cross-relaxation rate which depends on the spectral density (a measure of the molecular motions that the molecule is undergoing) consisting of both positive and negative terms. At $\omega\tau_c = 1$ these two terms are equal and the cross-relaxation rate is approximately zero. In contrast, under the spin lock conditions used in the ROESY experiment, the terms for the cross-relaxation rate are all positive. Therefore the intensity of the dipole–dipole coupling is always positive, varying from a theoretical intensity of 38% to 67% (Figure 2).¹⁷

This rather simple experiment had a great effect on the NMR study of peptides. Before the ROESY experiments, the only hope of observing an NOE was to change the conditions of the experiment either to slow down or speed up the molecular tumbling (i.e. to increase or decrease τ_c). Variation of temperature was sometimes successful, but often limited by the freezing or boiling points of the solvent. More viscous solvents were often employed. The addition of dimethyl sulfone to dimethyl sulfoxide greatly increased the viscosity, allowing for the measurement of NOEs. Other methods include using the greatly reduced eutectic point of an equal mixture of water and dimethyl sulfoxide (-70°C) to observe NOEs.¹⁹ This mixture has the advantage that the dielectric constant is identical to that of water at 25°C .

The illustration of the ROESY experiment eliminated the need for these methods. The dipole–dipole couplings, often called ROEs, could now be measured for small synthetic peptides without any modification of the solution. The temperature and solvent was chosen to enhance resolution and not for the development of distance restraints.

Another important advantage of the ROESY experiment with regard to the study of peptide structure is the unambiguous identification of cross peaks arising from chemical exchange. In this experiment, the cross peaks from the dipole–dipole coupling will be positive while those from the

Figure 2 The theoretical enhancement of NOEs and ROEs as a function of correlation time. A field strength of 500 MHz has been utilized

exchange of conformation will be of the opposite sign. This is important for the large number of peptides containing prolines, which can undergo exchange between a *cis* and *trans* configuration about the amide bond.

A complexity from the ROESY experiment is the appearance of cross peaks from scalar spin–spin couplings, which arise through Hartmann–Hahn matching, a condition that occurs when the two spins are experiencing equally effective spin lock fields. In the homonuclear case, this occurs when the spins have equal offsets from the spin locking field. Hartmann–Hahn matching is used to great advantage in the TOCSY (total correlation spectroscopy) experiment by which magnetization can be transferred through long spin–spin coupled systems: up to $^5J(\text{H,H})$ and $^6J(\text{H,H})$ are commonly observed for peptides. However, the Hartmann–Hahn or TOCSY peaks can greatly complicate the interpretation of ROESY spectra. To overcome this it is necessary to ensure the condition of unequal precession frequencies of the two spins. This can be accomplished through the use of a spin locking field comprised of pulses with very small flip angles²⁰ or which is very weak and off resonance.²¹ For synthetic peptides, placing the source of the spin locking field just downfield of the H- α region, will ensure that the resonances involved in the amide HN–H- α and H- α –side-chain (H- β , H- γ) correlations will have unequal precession frequencies. With the spin locking field located just to low frequency of the aromatic region, a second experiment is run, to minimize the occurrence of TOCSY peaks for amide HN–side-chain correlations.

If the ROESY interactions are to be used to develop internuclear distances, it is important that the field strength or resonance offset are varied and the cross-peak intensities examined carefully. A method has been described to remove the field dependence from the cross-peak intensity, commonly referred to as compensated ROESY.²² In addition, the

dependence of the cross-peak intensity on mixing time build-up rates, should be examined. This is important since ROESY is more susceptible to spin diffusion than the NOESY experiment.

5.2 Chemical Shift

There has been considerable utilization of chemical shifts in the examination of proteins. Long stretches of α -helices or β -sheets can be readily identified by chemical shift. The utility of chemical shifts to identify secondary structural elements is greatly increased when all of the chemical shifts of the peptide backbone are examined, including the α -protons, α - and β -carbon atoms and, to a lesser extent, the nitrogen atom and proton of the amide.

For peptides, the utilization of chemical shifts for conformational information is not clear-cut. The lack of long stretches of secondary structure seems to be the major complication. One abnormal chemical shift caused by the close proximity of one side chain will not be significant in a long stretch of α -helix; the general trend of chemical shifts can still be identified. In a peptide, the differentiation of the trend from the abnormal chemical shift is not possible. In addition, the greater surface area of peptides increases the effect of solvent on chemical shifts.

Chemical shifts are used in the study of the structure of synthetic peptides for the unambiguous identification of *cis/trans* isomerization about the amide bonds of Pro. The difference in the chemical shifts of the β - and γ -carbon atoms of the Pro can be used to identify the configuration about the amide bond. Large differences (8–10 ppm) are indicative of *cis* amide bonds, while small differences (4–6 ppm) indicate *trans* configurations.

5.3 Chemical Exchange

We have discussed the necessity of introducing constraints into peptides to allow for meaningful conformational analysis. Constraints are important if the conformations are to be useful in the development of structure–activity relationships. However, a consequence of peptide constraints, particularly for cyclic molecules, can be the introduction of different conformational isomers of significantly high energy not normally observed.

During our investigation of a series of 14-membered cyclic enkephalin analogs, additional sets of resonances were observed in the proton spectra.²³ From ROESY spectra, the additional sets of signals could be assigned to different configurational isomers; chemical exchange cross peaks were observed for the additional sets of resonances. From a careful inspection of the ROEs, the additional isomers could be assigned as arising from structures with *cis* peptide bonds. These peptides do not contain Pro or any other N-substituted amino acids and therefore *cis* peptide bonds were indeed unexpected. In fact, for one of the peptides examined, the major component contained a *cis* peptide bond; the all-*trans* isomer accounted for only 28% (two other structures with *cis* peptide bonds accounted for 51% and 21%, respectively) (Figure 3).²³

The rate of interconversion between the different isomers is fast on the NMR timescale. Chemical exchange peaks

Figure 3 Expansion of a two-dimensional ROESY spectrum illustrating chemical exchange between configurational isomers containing *cis* and *trans* amide bonds of the cyclic enkephalin analog, Tyr-c[-D-Glu-Phe-gPhe-D-retroLeu-] obtained in dimethyl sulfoxide at 40 °C with a mixing time of 300 ms. The NOEs (negative intensity) indicating the *cis* amide bonds have been labeled *cis*¹ and *cis*². The remaining cross peaks, positive intensity as is the diagonal, indicate chemical exchange between the different isomers

were observed in ROESY spectra with mixing times as small as 200 ms. The actual exchange rate can be calculated from the integration of the exchange peaks as a function of the mixing time from ROESY experiments. If resonances from one proton of both the *cis* and *trans* isomer are well separated, the measurement of the rate can be much more quickly determined with a one-dimensional saturation transfer experiment described many years ago by Forsén and Hoffman.²⁵ For the enkephalin analogs, the rates were measured for the conversion of both *cis* to *trans*, and *trans* to *cis*. The simple ratio of these rates should agree with the integrated intensity of the two configurational isomers. Measurement of the rate of chemical exchange at different temperatures then allowed for the calculation of the free energy of the transition. For the specific enkephalins values of 72–76 kJ mol⁻¹ were obtained. It is interesting to note that similar values were obtained for the *cis/trans* isomerization about the peptide bond of Pro containing linear peptides.²⁶

Since our original report of these unusual *cis* peptide bonds, many other groups have reported similar occurrences in cyclic peptides.²⁷ It is therefore important to keep the possibility of slow conversion between the different configurational isomers in mind when studying cyclic peptides. The observation of a *cis* peptide bond in a linear heptadecapeptide when associated with detergent micelles has also been reported.²⁸

5.4 Hydrogen Bonds

The presence of *intramolecular* hydrogen bonds is important for the determination of conformation. There are a number of methods to probe for the presence of hydrogen bonds. It was one of the earliest parameters used in the conformational examination of peptides, mainly because of the ease of the measurement. However, the interpretation and application of the data as a conformational restraint are not straightforward.

Amide protons involved in hydrogen bonds exchange with the solvent at a much slower rate than amide protons exposed to solvent. This simple fact can be used to probe the presence of intramolecular hydrogen bonds. A deuterated, protic solvent can be added and the intensity of the amide protons monitored as a function of time. Those amide protons exposed to solvent quickly disappear while those involved in hydrogen bonds remain for extended periods of time depending on the temperature, pH, and stability of the hydrogen bond.

Another method to probe for hydrogen bonds involves the change of the chemical shift of the amide protons with temperature. The method depends on the increase of molecular motion of the solvent with temperature. Those amide protons which are exposed and forming hydrogen bonds to the solvent are strongly affected by the change in temperature, since the increased molecular motion reduces the length of time that the hydrogen bond is present. Since the bonding to the solvent is present for shorter periods, the amide proton is less deshielded and there is a significant low frequency (upfield) shift. In contrast, the amide protons involved in *intramolecular* hydrogen bonds are much less affected by temperature change, and therefore the change in chemical shift is small.

The usefulness of temperature coefficients varies with solvent. The method works well for solvents that form strong bonds with the amides, particularly for those that can only act as donors (e.g. dimethyl sulfoxide). Temperature coefficients that are smaller than -2.0×10^{-3} ppm deg⁻¹ are assumed to be involved in an *intramolecular* hydrogen bond, while values greater than -4.0×10^{-3} ppm deg⁻¹ are thought to be solvent exposed.

For solvents that do not interact with the amide protons, temperature coefficients become more difficult to interpret. This is particularly true for chloroform. Although the trends are the same as those observed for dimethyl sulfoxide, the differences are much smaller because of the lack of strong interaction with the amide proton. The interpretation of temperature coefficients of peptides in aqueous solutions is difficult since water can act both as a donor and an acceptor for *intermolecular* hydrogen bonds. The difficulties in explaining temperature coefficients in water lie between that of dimethyl sulfoxide and chloroform. One of the most thorough examinations of temperature coefficients in many different solvents remains the work of Llinás and Klein.²⁹ The authors studied two cyclic hexapeptides in

trifluoroacetic acid, trifluoroethanol, chloroform, dimethyl sulfoxide, water, dimethylformamide, and pyridine solvents with a wide distribution of dielectric constants, pK_a s and abilities to act as hydrogen bond donors or acceptors.

It is important to realize that there are other reasons in addition to involvement in hydrogen bonds that could limit the exposure of an amide proton to the solvent. The amide proton may be buried within the peptide or shielded from the solvent by side chains. Neither of the methods mentioned above can differentiate between simple solvent shielding and hydrogen bonds.

The use of hydrogen bonds to develop conformational preference is also problematic. Only the donor, the amide proton of the hydrogen bond, can be experimentally identified. The acceptor of the hydrogen bond cannot be determined (although some studies to correlate the chemical shift of the carbonyl with the involvement in hydrogen bonds have been attempted). Therefore, the information that a particular amide proton is involved in a hydrogen bond can only be used as a secondary check: conformations of a peptide are developed using other experimental restraints (i.e. NOEs) and then the structures are examined. Those structures with amide protons that have low temperature coefficients involved in hydrogen bonds are selected. The experimental data are not used to generate conformations (i.e. conformational restraint).

Some attempts to use the presence of hydrogen bonds in calculations of conformations have appeared. An approach used in molecular dynamics simulations alters the partial charges assigned to the amide proton and nitrogen atom according to their temperature coefficients, decreasing the charge with larger temperature coefficients.³⁰ Therefore, those amide protons more likely to be involved in intramolecular hydrogen bonds (low temperature coefficients) will have higher partial charges and greater attraction to carbonyls from the Coulombic term in the force field.

Another approach utilizes the hydrogen-bonding information during a second refinement stage. During the first calculation only NOEs are used. From this initial structure the carbonyls which form hydrogen bonds to the amides that are experimentally determined to be involved in hydrogen bonds are found. Distance restraints between the amide and carbonyl are then included and the refinement repeated. Recently this approach has come under some criticism, since the structures produced are far better than justified from the experimental data.³¹ The hydrogen-bond restraints are too conformationally restrictive. It is important to note that with the requirement of planar peptide bonds, one hydrogen-bond restraint affects not only the two residues directly involved but also the residue preceding the donor and after the acceptor (Figure 4).

5.5 Solvent Studies

The large surface areas of peptides greatly increase the effect that solvent has on conformation. It is therefore imperative that the solvent be taken into consideration in the development of conformational preferences. Probably the best example of the large effect of solvent is cyclosporin A, a cyclic undecapeptide immunosuppressant, which has been examined in a number of different solvents. In chloroform, there is only one set of resonances, while in dimethyl sulfoxide there are seven different configurational isomers (arising from *cis* and

Figure 4 Illustration of the large effect of one hydrogen-bond restraint on peptide conformation. The planarity of the peptide bond, dihedral angle ω , produces a large effect on the preceding residue of the donor NH (bottom) and the residue following the acceptor carbonyl group (top)

trans isomerization about the many *N*-methylated residues in cyclosporin A). It is interesting to note that the conformation of cyclosporin A while bound to cyclophilin, the cytoplasmic receptor of cyclosporin A, contains only *trans* amide bonds.

Solvent titrations are often employed to investigate the effect of solvent on conformation. Titrations are advantageous since the assignments need only be made once; the resonances can usually be followed during the titration. It is important to consider the possibility of high, local concentrations of solvent during the titration. For example, for a peptide in a chloroform solution, the addition of a small amount of dimethyl sulfoxide has a large effect on the NMR observables (chemical shifts, NOE pattern); during the remainder of the titration only small changes are observed. The peptide is for all practical purposes completely solvated with dimethyl sulfoxide after the initial small addition.

We have examined many small cyclic peptides in dimethyl sulfoxide and carried out titrations with water. This provides a facile method to probe the conformations of a peptide in an aqueous environment when the peptide is not highly soluble in water (up to the concentrations required for NMR). For these constrained systems, only minor conformational changes are observed; most of the structural differences involve the hydrogen-bonding patterns of the peptide backbone.^{32–34} The different hydrogen bonds come about since water can act as both acceptor and donor, while dimethyl sulfoxide can only act as a donor. However, it is important to stress that these peptide systems are cyclic and constrained with 12 to 14-membered ring systems. If sufficient conformational constraint has been built into the molecule, only minor differences are expected with a change of solvent.

A minor difference was recently observed in the examination of a cyclic octapeptide [Pro-Pro-Tyr-Val-Pro-Leu-Ile-Ile-], where Val = valine, Leu = leucine, Ile = isoleucine. The peptide was studied in dimethyl sulfoxide and chloroform by NMR and extensive molecular dynamics simulations carried out in the same solvents as used in the NMR studies.³⁵ The overall conformations of the peptide in the two solvents were very similar. A difference was observed for the orientation of an amide bond in the middle of a β -turn; in chloroform the carbonyl group projected into the solvent, while in dimethyl sulfoxide there was a 180° rotation of the peptide bond and the amide proton projected into the solvent (i.e. in chloroform a β I-type turn, in dimethyl sulfoxide a β II-type turn). The computer simulations clearly indicate the basis for this

change; there are atom-specific interactions between chloroform and the carbonyl group, while dimethyl sulfoxide only forms *intermolecular* hydrogen bonds to the amide proton. The solvent stabilizes the different conformations through interactions with the central amide group of the β -turn.

5.6 Coupling Constants as Conformational Restraints

As discussed above, there are a smaller number of NOEs for synthetic peptides than are commonly observed for large biomolecules. To overcome this fact, the use of coupling constants as conformational constraints has recently been reported. The addition of coupling constants as experimental restraints, in addition to NOEs, has greatly improved the structures obtained for small peptides.

Coupling constants provide conformational information about the dihedral angles subtended by the coupled atoms. The equation most often used, developed by Karplus from simple valence bond electron calculations many years ago,³⁶

$$^3J = A \cos^2(\theta) + B \cos(\theta) + C \quad (2)$$

relates the coupling constant to the dihedral angle (θ) subtended by the coupled atoms. However, the application of this equation to develop conformational information is not straightforward.

The early uses of this equation were limited. Similar to the application of temperature coefficients, after the development of a conformation from NOEs, the dihedral angles were used to calculate the coupling constants and the agreement with the experimental values examined. The agreement was almost always found to be good, mainly because of the large range of values that are produced by the Karplus equation. Since only the absolute value of the dihedral angle is important, two answers are produced for every θ , which in addition to the quadratic nature of the equation, produces four answers (depending on the *A*, *B*, and *C* coefficients and the measured coupling constant). If a reasonable error of 20° is added to each of these answers, it quickly becomes possible to obtain a wide range of acceptable dihedral angles. The agreement between the experimental and calculated coupling constants is therefore not surprising.

To address the wide range of allowed values, the measurement of additional coupling constants about the same dihedral angle has been undertaken. Recently a large number of new methods have appeared to measure heteronuclear couplings for samples in natural abundance.^{37,38} Using this approach, only the dihedral angles that are in agreement with all of the couplings are retained. This usually allows some of the solutions to the Karplus equation to be eliminated. However, the coupling constants are still being employed as a secondary measure of the fit of the experimental observables with a structure; the coupling constant data are not employed to produce the conformation (i.e. conformational restraint).

The application of dihedral angle restraints was one of the first uses of coupling constants in calculations. For large or small coupling constants, a range of allowed dihedral angles was chosen and a penalty function applied. For the most commonly measured coupling constant, $^3J(\text{HN}, \text{H}-\alpha)$, a value larger than 8.5 Hz indicated a small range centered at -120°; for couplings smaller than 6.0 Hz, the range of values was increased to -160° to -40°.

A more direct application of coupling constants in structural refinement calculations was introduced by Kim and Prestegard.³⁹ The penalty function proposed is similar to that utilized for NOE distance restraints;

$$V_J = \frac{1}{2} K_J (J_{\text{exp}} - J_{\text{theo}})^2 \quad (3)$$

where J_{exp} is the experimental coupling constant, K_J is a force constant to weight each coupling individually, and J_{theo} is the theoretical coupling calculated using the Karplus equation. The difference between the experimental and theoretical values is minimized during the refinement calculation. This approach allows all of the coupling constants to be utilized in the refinement calculations without any approximations of the ranges of dihedral angles that are appropriate.⁴⁰ An illustrative penalty function is shown in Figure 5.

There are numerous homonuclear and heteronuclear coupling constants that can be measured for the ϕ and χ_1 dihedral angles [e.g. $^3J(\text{HN}, \text{H}-\alpha)$, $^3J(\text{HN}, \text{C}-\beta)$, $^3J(\text{C}', \text{H}-\alpha)$ and $^3J(\text{C}, \text{H}-\beta)$, $^3J(\text{N}, \text{H}-\beta)$, $^3J(\text{H}-\alpha, \text{H}-\beta)$]. For the other backbone dihedral angle, ψ , there are a limited number of three-bond couplings that can be measured. Those that can be measured, e.g. $^3J(\text{N}, \text{H}-\alpha)$, are very small and therefore have a large associated error. It was with this in mind that we developed the possibility of using one-bond coupling constants as conformational constraints. It was illustrated many years ago by Egli and von Philipsborn⁴¹ that the one-bond coupling between the α -proton and α -carbon atom depends both on the ϕ and ψ dihedral angles, as shown below,

$$^1J(\text{C}-\alpha, \text{H}-\alpha) = 14.0 \cos^2(\phi + 30^\circ) - 5.2 \cos^2(\psi - 30^\circ) + 136.2 \quad (4)$$

We have used this relationship to develop conformations with the sole use of coupling constants that are similar to those calculated with NOEs.⁴² This method has the advantage of the great ease with which the one-bond coupling can be

Figure 5 Example of the penalty function used for coupling constant restraints. The penalty 'energy' is illustrated for two coupling constants about the ϕ dihedral angle: $^3J(\text{HN}, \text{H}-\alpha)$ (broken line) and $^3J(\text{HN}, \text{C}-\beta)$ (dotted line). The sum of the two couplings is shown as the solid line

measured [i.e. the acquisition of a heteronuclear multiple quantum coherence (HMQC) experiment without decoupling of the carbon resonances]. There are limitations to the use of the one-bond coupling, including the large number of minima produced for one coupling constant which is magnified when experimental error is taken into account.

In addition to the conformational information obtained from coupling constants, dynamics can also be probed. This is particularly important for fast conformational averaging taking place on the NMR timescale, a situation addressed in the computer refinement section above. With the measurement of both NOEs and coupling constants, the presence of fast conformational exchange can be unambiguously identified.

Coupling constants and NOEs depend on different structural factors; the dihedral angle subtended by the coupled atoms and the internuclear distance between the dipole-coupled atoms, respectively. These quantities average differently in the presence of conformational exchange. The NOEs average as the sixth inverse power of the distance between the dipoles (i.e. R^{-6}), while the coupling constant averages as the cosine series of the subtended dihedral angle θ (i.e. $\cos^2 \theta$ and $\cos \theta$). The average structures consistent with the NOEs are not the same as those consistent with the coupling constants.⁴³ The application of the two restraints therefore provides a method of identifying fast conformational averaging on the NMR timescale.

5.7 Determination of Configuration

Many of the synthetic modifications discussed above produce at least two possible configurations with peptidomimetic residues incorporated. In most cases the two can be separated using HPLC or other methods. The task becomes the unambiguous assignment of the correct configuration to the isolated molecules. The most straightforward method is to measure as many experimental restraints as possible for the isomers and simply fit the restraints to both possible choices. This approach worked in the examination of the Pro mimetic, 2-aminocyclopentanoic acid, which was noted above.⁴ The synthetic routes can be configurationally controlled to produce only the *cis* or only the *trans* isomer. However, there are two possibilities for the *cis* (*R,S* and *S,R*) and the *trans* (*S,S* and *R,R*) isomers. Each of the isomers were separated and biologically assayed. Since there was a wide variation in the biological activities, it was important to determine the configuration of the centers of the 2-aminocyclopentanoic acid residues; the configurations have a great impact on the topological arrangement of the residues before and after them in the peptide sequence. From the distance restraints developed from the NOEs measured for each isomer, the assignment of the relative chirality was obtained. The assignment is illustrated in Figure 6. The lowest energy structures found from the molecular dynamics simulations are shown. Three key NOEs, which allow for the differentiation between the two isomers are also shown in the Figure.

The problem with this approach is that the number of possibilities increases as a function of 2^N , where N is the number of unknown chiral centers. It is also important that the region of interest be high in proton density, so that there are many experimental restraints involving the questionable chiral centers. The method proposed above will often fail when the chiral center of interest has no proton directly attached.

Figure 6 Illustration of the three NOEs that allowed the assignment of the chirality of the 2-aminocyclopentanoic acid residue ($\beta\text{Ac}^5\text{c}$). The NOEs are fulfilled by the R,S analog, not by the S,R analog. The NOEs are: Tyr H- α –Pro H- α , $\beta\text{Ac}^5\text{c}$ H- α –Phe HN, and $\beta\text{Ac}^5\text{c}$ H- β –Pro H- δ

The resolution of the peptide conformation is greatly enhanced when the protons of side-chain methylene groups can be stereospecifically assigned. Without these assignments, distances calculated for these protons must be adjusted to allow for both possibilities, the pro- R and pro- S protons. This is accomplished by adding a distance correction, often 0.9 Å, to the upper distance restraint.^{44,45} This seemingly small addition has a significant effect on the conformations produced from the refinement calculations. The more loosely defined distances allow for many more possible conformations. The same is true for the diastereotopic methyl groups of the amino acids Leu and Val. The upper limit distance restraints for a methyl group not diastereotopically assigned should be increased by over 1.5 Å. The conformational information of such a NOE is therefore greatly reduced by the lack of diastereotopic assignments.

There are a number of methods of making diastereotopic assignments. The least ambiguous method involves the measurement of coupling constants. For β -methylene protons, the homonuclear $^3J(\text{H-}\alpha,\text{H-}\beta)$ and heteronuclear $^3J(\text{C}',\text{H-}\beta)$ coupling constants usually provide for the unambiguous assignment. It is often the case that only an estimate of the size of the heteronuclear coupling is sufficient. For the assignment of the methyl groups, heteronuclear $^3J(\text{C},\text{H})$ coupling constants can be measured with the ω 1-filtered TOCSY experiment.⁴⁶ In this experiment, the proton magnetization is filtered, selecting only the protons coupled to the heteronuclei (i.e. ^{13}C), before the TOCSY sequence which mixes the magnetization of all protons. This produces a standard TOCSY spectrum with the cross peaks split in the F_1 dimension by $^1J(\text{C},\text{H})$ (140 Hz) and in the F_2 dimension by the long-range coupling constant, $^3J(\text{C},\text{H})$. This experiment is ideal for the assignment of the side-chain methyl groups of Leu and Val, since it is quite sensitive when the heteronuclei, here the carbon, have three protons. The measurement of $^3J(\text{C-}\gamma,\text{H-}\alpha)$ for Val and $^3J(\text{C-}\delta,\text{H-}\beta)$ for Leu, along with the homonuclear couplings, usually allow for the unambiguous diastereotopic assignment of the methyl groups of these residues.

For peptides where the measurement of coupling constants is not possible, there is a very powerful method often used in the examination of proteins. It involves the use of floating chiralities.⁴⁷ During the computational refinement the methylene protons or methyl groups can switch stereospecific positions driven solely from the distance restraints of the NOEs. For proteins, where the number of NOEs is large,

the method is extremely useful. For peptides, the sole use of NOEs usually is not sufficient to allow for an unambiguous assignment. We have found that the addition of coupling constant restraints, in addition to the NOEs, greatly increases the efficiency of the floating chirality procedure.⁴⁸ The low-frequency and high-frequency proton signals are arbitrarily assigned to pro- R or pro- S for both the NOE and coupling constant restraints. Then during the simulation the chiralities are allowed to change positions, i.e. float. One note of caution must be made with the use of floating chiralities; the method will produce an answer (i.e. one proton will be pro- R , the other pro- S), no matter what the extent of the experimental restraints is. The number of restraints gives little insight into the confidence of the assignment. Also important is the nature of the restraints, a few restraints from different angles or orientations will be of more use than a larger number of NOEs from one direction. The method that we employ to examine the confidence in the diastereotopic assignment is a graphical representation of the NOEs for each of the chiral centers.

1 INTRODUCTION

Thioredoxins and glutaredoxins are ubiquitous small proteins involved in redox reactions in cells and viruses, including ribonucleotide reduction, sulfate metabolism, and both oxidative and reductive thiol–disulfide reactions with proteins.^{1,2} Recent work implicates thioredoxin in cellular redox control mechanisms and also in mammalian virus systems, with possible applications in therapeutics.³ The active sites of thioredoxin and glutaredoxin are similar, consisting of two cysteine (Cys) residues which are separated by two other residues and which are present as a disulfide in the oxidized protein and as a dithiol in the reduced protein. The active-site sequence in thioredoxin is -Cys-Gly-Pro-Cys- (where Gly = glycine, Pro = proline) and in glutaredoxin is -Cys-Pro-Tyr-Cys- (where Tyr = tyrosine).²

NMR spectra of *Escherichia coli* thioredoxin were reported as early as 1976,⁴ but extensive NMR studies on these proteins were not made until the advent of high-field spectrometers in the 1980s. The NMR spectrum of a protein gives information on the three-dimensional (3D) structure (see *Structures of Larger Proteins, Protein-Ligand, and Protein-DNA Complexes by Multi-Dimensional Heteronuclear NMR*). Structure determination has provided a major impetus in the study of thioredoxins and glutaredoxins by NMR, since, with the exception of the well-known X-ray crystal structure of the oxidized form of *E. coli* thioredoxin,⁵ X-ray crystallography could not be used to derive structures because crystals were not formed. Oxidized *E. coli* thioredoxin was crystallized in the presence of Cu²⁺,⁶ crystals of reduced *E. coli* thioredoxin have not been found under the same conditions due to the redox reaction between the copper ions and the protein dithiol. Its 3D structure has therefore been solved by NMR spectroscopy,⁷ and a recent high-resolution structure determination by NMR for both oxidized and reduced *E. coli* thioredoxin⁸ has allowed direct comparison of the two forms of the protein under identical conditions.

The structure of reduced human thioredoxin cloned from T-lymphocytes and overexpressed in *E. coli* has also been solved by NMR,⁹ and the structures of both oxidized and reduced forms of a mutant protein have recently been published.¹⁰ Although the glutaredoxin from T4 bacteriophage

has been crystallized and its structure determined by X-ray crystallography,¹¹ *E. coli* glutaredoxin has not been crystallized; the structures of both oxidized and reduced glutaredoxin have recently been determined by NMR.^{12,13}

The NMR spectrum of a protein also gives a great deal of useful site-specific information, and can be used to probe enzyme mechanism and function and ligand binding. A number of such studies have been performed for thioredoxins and glutaredoxins and are summarized in this article, together with work on the structures of these proteins.

2 NMR OF *ESCHERICHIA COLI* THIOREDOXIN

2.1 Solution Conditions for NMR

The stability and small size of *E. coli* thioredoxin (108 amino acids, M_r 11 700) make it a suitable candidate for NMR spectroscopy. Both the oxidized and reduced forms are soluble to approximately 4 mM at pH 5.7 in 100 mM phosphate buffer^{4,14} and to 5–8 mM in 150 mM NaCl/20 mM phosphate, pH 5.7.¹⁵ Dithiothreitol (DTT)-free reduced thioredoxin is prepared from the oxidized form of the protein by the addition of DTT and subsequent passage of the solution through a short column of Sephadex G25 equilibrated under argon.¹⁶ The NMR spectrum is well dispersed with narrow resonance lines under these conditions. At pH values below 5.5 broadening of resonances in the NMR spectrum is observed, indicating the onset of aggregation, which occurs as the pI (~ 4) is approached.⁴ The NMR spectrum as a whole is unaffected by pH changes up to pH 10, indicating that the structure of the protein is largely unaffected by pH in this range.¹⁷ Certain resonances shift with pH due to the titrations of the N-terminal amine, the single histidine residue, and a buried aspartate near the active site in both oxidized and reduced thioredoxins, and by the titrations of the two thiol groups in reduced thioredoxin.¹⁷

2.2 Resonance Assignments and Structure Determination

A number of methods have been used for resonance assignment of *E. coli* thioredoxin. Pioneering studies in the use of isotope labeling were performed with oxidized thioredoxin, including the development of random fractional deuteration as a means of spectrum simulation and stereospecific assignment,^{15,18,19} and specific labeling of amino acids as a means of sequential resonance assignment.^{20,21} Backbone and C- β ,H ¹H resonance assignments of the oxidized form of *E. coli* thioredoxin were largely completed using these methods combined with conventional ¹H two-dimensional (2D) spectroscopy.¹⁵ Proton-only 2D NMR was used to obtain complete ¹H assignments for both oxidized and reduced *E. coli* thioredoxin,¹⁶ and these assignments were used as a basis for the calculation of the solution structure of reduced *E. coli* thioredoxin using distance and dihedral angle restraints from ¹H 2D NOESY and COSY spectra.⁷ The NMR spectra of reduced and oxidized *E. coli* thioredoxin are very similar, differing only in the region of the active site,^{14,16} and the NMR solution structure of reduced thioredoxin is virtually identical to the X-ray crystal structure of oxidized thioredoxin.⁵ Even

in the active site region where the NMR spectra of the two forms are different, the backbone conformations of the two forms of the protein are superimposable, and there are only the most subtle differences in the disposition of the side chains in this region. A total of 853 interresidue and 391 intraresidue distance constraints and 43 dihedral angle constraints were used in the calculation of the structure using the program DISGEO, and the resulting structures were refined with molecular dynamics (AMBER), for a final average rms deviation from the average structure of 0.564 for backbone heavy atoms of residues 3–108.⁷

The NMR solution structure of reduced *E. coli* thioredoxin represents probably one of the largest that has been calculated using ¹H 2D methods alone. Resonance overlap and the resulting ambiguities in estimates of internuclear distance lower the number of available distance and dihedral angle restraints, and hence the potential resolution of the structure. The additional resolution provided by the use of protein uniformly labeled with ¹³C and ¹⁵N^{22,23} allows the addition of a significantly greater number of restraints to the calculation, resulting in a higher resolution structure. High-resolution structures have recently been calculated, using the program DIANA followed by refinement with molecular dynamics (AMBER), for both oxidized and reduced *E. coli* thioredoxin⁸ using 2846 (reduced) and 2710 (oxidized) NOE distance restraints from 3D ¹³C and ¹⁵N heteronuclear NOESY spectra and 131 (reduced) and 136 (oxidized) dihedral angle restraints obtained from coupling constants. Final backbone average rms deviations from the average structure of 0.29 Å and 0.35 Å were obtained for the well-defined residues (4–107) of 30 reduced and oxidized thioredoxin structures respectively.⁸ A superposition of 20 of each of the calculated structures is shown in Figure 1.

2.3 Nitrogen-15 Relaxation and Polypeptide Backbone Dynamics

The backbone and tryptophan side-chain dynamics of oxidized and reduced thioredoxin have been estimated using uniformly ¹⁵N-labeled protein,²⁴ and show a number of regions, especially in turns and loops, where backbone flexibility is high compared with that of the polypeptide present in ordered secondary structure. The rather low proportion of flexible regions in thioredoxin is consistent with the exceptionally high thermal stability of this protein in either oxidation state.²⁵ The active site loop is also apparently flexible, but measurements are hampered because the sequence contains Gly and Pro, for which the ¹⁵N relaxation parameters are not measurable. Differences in the flexibility of loops adjacent to the active site occur between the oxidized and reduced forms of the protein (see Section 2.5).

2.4 pH-Dependence of the Mechanism of Thioredoxin Dithiol–Disulfide Exchange

The mechanism of reduction by thioredoxin is thought to proceed via nucleophilic attack by a thiolate anion belonging to Cys-32, with formation of a mixed disulfide.²⁶ Control of the pH in the active site region is therefore likely to be crucial to the reaction. The pK_a for deprotonation of Cys-32 was shown in chemical modification studies to be considerably lowered from normal, to a value of about 6.7,²⁶ consistent with its postulated role as primary nucleophile. However, the mechanism is apparently quite complex, as shown by an NMR study of reduced and oxidized thioredoxin as a function of pH between 5.7 and 10.¹⁷ pK_a values of 7.1 and 8.4 were obtained

Figure 1 Stereo view showing the best-fit superposition for residues 4–107 of 20 NMR solution structures of reduced *E. coli* thioredoxin (yellow) and oxidized thioredoxin (blue) obtained using the distance geometry program DIANA followed by molecular dynamics refinement with AMBER. The active site (residues 32–35) is at the bottom right of the structure. (Reproduced by permission from Jeng et al.⁸)

for two groups titrating in the active site region of reduced thioredoxin, consistent with the values previously obtained for the two active site thiols.²⁶ However, a third group also titrates in the active site region, giving a pK_a of 7.5 in oxidized thioredoxin and ~ 7.1 in reduced thioredoxin. Mutant studies by NMR²⁷ and other methods^{28,29} indicate that this titrating group is most likely the buried carboxyl group of aspartic acid (Asp)-26, which is thus revealed as an important factor in the pH control of the mechanism of *E. coli* thioredoxin.

2.5 Structural and Functional Differences between Oxidized and Reduced Thioredoxin

There are a number of functional differences between oxidized and reduced thioredoxin that are not due entirely to the presence or absence of thiol groups. Reduced thioredoxin is required for the assembly of filamentous bacteriophages^{30,31} and is an essential subunit of the DNA polymerase induced by T7 phage.³² Oxidized thioredoxin does not function in these systems. Mutants where one or both Cys residues are replaced with serine (Ser) or alanine (Ala) are partially functional,^{31,33} suggesting some structural or conformational difference between the two forms that can be differentiated in the phage systems. The extremely small structural differences between the two forms of thioredoxin is illustrated in Figure 1. Indeed, the only significant difference appears to be a slight change in the backbone configuration at the active site due to the change in position of the reduced sulfur of Cys-32,⁸ as shown in Figure 2. In the absence of a strongly marked change in the structure, the difference may lie in the relative mobility of the polypeptide chain in the vicinity

of the active site. Backbone dynamics of both oxidized and reduced thioredoxin were studied using ¹⁵N relaxation²⁴ and revealed a significant difference in the local flexibility of several of the loops that abut the active site. In particular, the sequence that precedes the highly conserved *cis*-Pro at position 76 is more flexible in reduced thioredoxin, suggesting that certain structural states may be kinetically accessible to reduced thioredoxin but not to the oxidized form due to the constraint imposed by the disulfide bond. This interpretation is borne out by a comparison of the rates of amide proton hydrogen exchange in the two forms of the protein,³⁴ which indicate a significantly greater protection in the active site region in oxidized thioredoxin, consistent with lower flexibility of the polypeptide chain. If one or more of these low-energy states was required for thioredoxin function in the filamentous and T7 phage systems, then reduced thioredoxin would be functional and the oxidized form would not. A recent NMR study of a double Cys-to-Ser mutant of *E. coli* thioredoxin²⁷ revealed that its behavior most closely resembled reduced rather than oxidized thioredoxin, consistent with these ideas and with previous functional studies of mutants.³¹

3 NMR OF HUMAN THIOREDOXIN

3.1 Solution Conditions for NMR

The thioredoxin cloned from human T-lymphocytes (105 amino acids) is approximately 25% homologous with the *E. coli* protein, mainly in the active site region.³⁵ Reduced human thioredoxin is soluble to at least 2 mM and solutions prepared

Figure 2 Stereo superposition (on the backbone of the entire molecule, residues 4–107, as in Figure 1) of the active site, including selected side chains, for 20 structures each of reduced (yellow) and oxidized (blue) thioredoxin. The disulfide bond is indicated by the hatched red and black bars, and the positions of the Cys sulfur atoms in reduced thioredoxin are shown by yellow spheres. (Reproduced by permission from Jeng et al.⁸)

in 100–150 mM phosphate buffer containing 0.2 mM DTT under argon appear to be stable at pH 7.0 or 5.5 for at least 2 months, over a temperature range of 4–50 °C.³⁶ Solubility is reduced at pH values below 5.6.³⁷ Only the reduced form of unmodified human thioredoxin has so far been studied by NMR, because of the presence of three Cys residues in addition to the two in the active site. The presence of these additional thiol groups causes problems with aggregation of the protein upon oxidation. The recombinant human thioredoxin isolated from an *E. coli* expression system is heterogeneous at the N-terminus, with about 30% of the protein containing an extra methionine residue,³⁶ although the N-terminal methionine is processed more efficiently during bacterial growth in minimal media.³⁸ A triple Cys-to-Ala mutant of human thioredoxin has been constructed to allow NMR studies of both oxidation states of human thioredoxin.³⁹

3.2 Resonance Assignments and Structure Determination

The ¹H resonances of reduced human thioredoxin were initially assigned and a description of the secondary structure was obtained using ¹H 2D methods.³⁶ Extensive ¹⁵N assignments and coupling constant measurements have been made for reduced human thioredoxin,³⁸ and a high-resolution structure has been calculated.⁹ A family of NMR solution structures of reduced human thioredoxin (Figure 3) were calculated using a hybrid distance geometry–simulated annealing method⁹ with 1294 interresidue and 689 intraresidue distance restraints obtained from NOESY and ¹⁵N heteronuclear multiple quantum coherence (HMQC)–NOESY experiments and 241 torsion angle restraints obtained from coupling constants. Proton and ¹⁵N resonance assignments have also been made for the reduced form of a triple mutant of human thioredoxin, in which the three Cys residues other than those in the active site have been mutated to Ala residues,³⁹ and structures have been calculated for the oxidized and reduced forms of this mutant¹⁰ using 2571 distance restraints, 273 torsion angle restraints, and 89 ³J(HN-α) coupling constant restraints for the reduced form, and 2649 distance restraints, 278 torsion angle restraints, and 91 ³J(HN-α) coupling constant restraints for the oxidized form. The backbone atomic rms deviations from the mean structure were 0.19 Å and 0.18 Å respectively for 40 structures of reduced and oxidized mutant thioredoxin.¹⁰ The

Figure 3 Stereo view (approximately the same view as Figure 1) showing the best-fit superpositions of the backbone (N, C-α, and C) atoms of 33 NMR solution structures of reduced human thioredoxin obtained by a distance geometry–simulated annealing method. (Reproduced by permission from Forman-Kay et al.⁹)

structure consists of a 5-stranded twisted β-sheet surrounded by four α-helices and the overall structure is similar to those of *E. coli* thioredoxins.^{5,7} The major differences between the thioredoxins from these two different sources is in helices α₁ and α₃, which are longer and more regular in human thioredoxin. The active site conformations are all very similar, as would be expected from the high degree of sequence homology in this region.

3.3 Bound Water Molecules in the Structure of Human Thioredoxin

The positions of relatively tightly bound water molecules in the structure of reduced human thioredoxin have been determined using 3D ¹H–¹⁵N ROESY–HMQC spectroscopy.⁴⁰ A number of backbone amide protons are in close proximity to a total of four best-fit bound water molecules in structures recalculated to include them. Two of the water molecules could be located in fairly tight families, one in the β-bulge between strands 4 and 5 of the β-sheet and one associated with the C-terminal ends of the α₂ and α₄ helices. Of the other two water molecules, one occupies two positions near the loop between α₁ and β₂ and the other occupies two positions close to the N-terminus of α₂, near the active site. Several of the positions found for the bound water molecules in the solution structure of reduced human thioredoxin⁴⁰ are similar to those found in the X-ray crystal structure of oxidized *E. coli* thioredoxin.⁵

3.4 Electrostatics and Redox Function in Human Thioredoxin

An extensive study of the pH-dependent behavior of reduced human thioredoxin was made using ¹H and ¹⁵N NMR spectroscopy.³⁷ Inclusion of measurements on solutions of pH lower than 5.6 allowed determination of the pK_a values of aspartate and glutamate side chains, although many of the titration curves exhibit complex behavior due to the effects of interacting titrating groups. Unlike *E. coli* thioredoxin,¹⁷ no clear-cut effect of the titration of the buried carboxyl side chain of Asp-26 was observed, and the pK_a of the thiol of Cys-32 was measured to be 6.3, lower than the value for *E. coli* thioredoxin. The anomalously low pK_a for the Cys-32 thiol was attributed³⁷ to an interaction of the S-γ atom of Cys-32 with the amide group of Cys-9 seen in the solution structure of reduced human thioredoxin.⁹

4 NMR OF *ESCHERICHIA COLI* GLUTAREDOXIN

4.1 Solution Conditions for NMR

E. coli glutaredoxin (85 residues, M_r ~10 000) is a heat-stable acidic protein which reacts with glutathione and is responsible for mediating many glutathione-dependent redox functions in the cell. There is very little sequence homology between *E. coli* glutaredoxin and thioredoxin, although both contain an active site disulfide/dithiol group. The solution conditions required for NMR studies of glutaredoxin are less than optimal for structure determination.⁴¹ Oxidized

glutaredoxin is insoluble at pH values below 5.5 and the NMR spectrum shows evidence of aggregation at pH 6.0. The protein appears to be stable and monomeric at pH 7.0 and 28 °C, at a concentration of 2.5 mM in 50 mM phosphate buffer. Reduced glutaredoxin is prepared from the oxidized form of the protein at 4 °C by the addition of DTT followed by buffer exchange in an ultrafiltration cell.¹² Final solution conditions were 3 mM protein in 50 mM phosphate, pH 7.0, 28 °C.

4.2 Resonance Assignments and Structure Determination

Nearly complete resonance assignments have been made for oxidized⁴¹ and reduced¹² *E. coli* glutaredoxin, using mainly ¹H 2D methods, with the addition of 3D ¹⁵N NOESY spectra for the resolution of ambiguities in NOE assignments and for measurement of ³J(HN- α) coupling constants. Initial NMR spectra showed some heterogeneity, as glutaredoxin

is apparently susceptible to proteolysis; this problem was overcome by the use of protease inhibitors.⁴¹ Additional heterogeneity in the NMR spectra of oxidized glutaredoxin was also due to the presence of about 10% of a form elongated at the N-terminus or to conformational isomerism.⁴¹ No conformational heterogeneity was reported for reduced glutaredoxin.¹² Three-dimensional structures were calculated for both forms of glutaredoxin using the program DIANA followed by simulated annealing. For oxidized glutaredoxin, 563 interresidue and 219 intraresidue distance constraints and 74 dihedral angle constraints were used.¹³ For reduced glutaredoxin, 402 interresidue and 221 intraresidue distance constraints and 191 dihedral angle constraints were used.¹² The structure of glutaredoxin, shown in Figure 4, consists of a 4-stranded β -sheet and three helices, and is very similar in both oxidized and reduced forms of the protein.¹³ Exchange rates of slowly exchanging amide protons are similar, indicating similar hydrogen-bonding patterns, but

Figure 4 Stereo views of the 20 conformers used to represent the solution structure of (a) reduced and (b) oxidized *E. coli* glutaredoxin obtained using the program DIANA followed by simulated annealing. The complete polypeptide backbone from residues 1 to 85 is shown. The conformers 2–20 were superimposed with conformer 1 (which has the smallest residual violations) for pairwise minimal rms deviation of the backbone atoms N, C- α , and C' of residues 1–8, 13–43, and 60–83. The active site (residues 11–14) is at the top right of the structure. (Reproduced by permission from (a) Sodano et al.¹² and (b) Xia et al.¹³)

differences in local dynamics are evident near the active site and the C-terminal α -helix.¹³ A comparison of Figures 1–4 shows that, despite the low sequence homology between glutaredoxin and thioredoxin, the overall folds of thioredoxin and glutaredoxin are quite similar.

4.3 Structure of a Mixed Disulfide Complex of Glutathione and Glutaredoxin

As for thioredoxin, the mechanism of thiol–disulfide exchange of glutaredoxin was thought to proceed via a mixed disulfide intermediate between one of the active site thiols and a molecule of glutathione.⁴² In order to probe the structure of such an intermediate, a mutant glutaredoxin was prepared with one of the active site cysteines, Cys-14, substituted by Ser. The physiological substrate, glutathione, could then be bound to the remaining cysteine, Cys-11, forming a mixed disulfide which ought to have the same structure as that of the wild-type, but which is stable since reaction of the second thiol (now a Ser) with a second molecule of glutathione and release of the oxidized glutathione dimer is not possible. The C14 $\rightarrow$ S glutaredoxin mutant and the mixed disulfide complex with glutathione have been prepared and characterized by NMR,⁴² and the structure of the complex has recently been reported.⁴³ Nitrogen-15 NMR studies⁴² confirmed that the glutathione molecule is attached via a disulfide bond to Cys-11, and the structure shows that it lies along a shallow cleft in the protein that includes a number of hydrophobic residues.⁴³

1 INTRODUCTION

NMR spectroscopy with biological macromolecules has been limited to relatively small structures, with molecular weights up to about 50 kDa, and the size distribution of the approximately 2500 NMR deposits in the Protein Data Bank peaks near a molecular weight of 10 kDa.¹ In spite of this limitation, NMR is one of the principal experimental techniques in structural biology.^{2,3} Nonetheless, the availability of solution NMR techniques for studies of larger structures is of keen interest, in particular for applications in the newly emerging field of structural and functional genomics.⁴ With the presently described principles of transverse relaxation-optimized spectroscopy (TROSY) the size limit for molecular structures that are amenable to high resolution NMR studies in solution has been extended severalfold.^{5–7} TROSY-based NMR experiments are particularly well suited for applications with proteins and nucleic acids,⁸ which are a main focus also in the present article.

2 THE FOUNDATIONS OF TRANSVERSE RELAXATION-OPTIMIZED SPECTROSCOPY (TROSY)

At the high magnetic fields typically used for studies of proteins and nucleic acids, chemical shift anisotropy (CSA) of ^1H ,

^{15}N and ^{13}C nuclei can be a significant source of transverse relaxation, in addition to the omnipresent relaxation due to dipole–dipole coupling. As a consequence the individual multiplet components in heteronuclear two-spin systems, such as ^{15}N – ^1H in amide groups and aromatic ^{13}C – ^1H moieties, may have different transverse relaxation times (Figure 1), and in large structures studied at high magnetic fields these individual relaxation rates are actually largely different.⁷ Heteronuclear decoupling, which is routinely applied in conventional NMR spectroscopy,⁹ will then lead to a deteriorated averaged signal due to the mixing of the different relaxation rates. In TROSY-type experiments the multiplet structures (Figures 1 and 2) are not decoupled, and only the narrowest, most slowly relaxing line of each multiplet is retained.¹⁰

2.1 Theory

For a system of two scalar-coupled spin $1/2$, I and S , a straightforward description of TROSY can be obtained with the use of single-transition, zero-quantum and double-quantum basis operators.⁷ In this basis the individual transverse relaxation rates of all six coherences in a coupled two-spin system

Figure 1 (a) Diagram of the energy levels 1–4 of a system of two scalar-coupled spins $1/2$, I and S , with indication of the transverse relaxation rates, R , of the individual transitions. The abbreviations ZQ and DQ stand for zero-quantum and double-quantum transitions. (b) Cross-peak of a backbone amide moiety from a two-dimensional ^{15}N , ^1H -HSQC spectrum of uniformly ^2H , ^{13}C , ^{15}N -labeled 7,8-dihydroneopterin aldolase (DHNA) from *Staphylococcus aureus* measured without ^1H and ^{15}N decoupling. DHNA is a homooctameric protein of molecular weight 110 kDa.⁴⁴ The NMR sample contained 0.4 mM DHNA octamer, solvent 90% H_2O /10% D_2O , pH = 6.5, $T = 20^\circ\text{C}$, ^1H frequency = 750 MHz. The relaxation rates that are effective for the individual multiplet components are indicated at the top and on the left. The cross marks the center of the multiplet, i.e., the position of the single-component cross peak in a ^1H and ^{15}N broadband decoupled spectrum

(Figure 1) can readily be expressed. Taking only dipole–dipole coupling and CSA relaxation into account, the differential equation (1) describes the time evolution of the system in the slow tumbling limit, where we retain only terms with the spectral density at zero frequency, $J(0)$:

$$\frac{d}{dt} \begin{bmatrix} \langle I_{13}^{\pm} \rangle \\ \langle I_{24}^{\pm} \rangle \\ \langle S_{12}^{\pm} \rangle \\ \langle S_{34}^{\pm} \rangle \\ \langle DQ^{\pm} \rangle \\ \langle ZQ^{\pm} \rangle \end{bmatrix} = - \begin{bmatrix} \pm i\omega_{13}^I + R_{13}^I & & & & & \\ \pm i\omega_{24}^I + R_{24}^I & & & & & 0 \\ \pm i\omega_{12}^S + R_{12}^S & & & & & \\ \pm i\omega_{34}^S + R_{34}^S & & & & & \\ 0 & \pm i\omega_{14}^{DQ} + R_{14}^{DQ} & & & & \\ & \pm i\omega_{23}^{ZQ} + R_{23}^{ZQ} & & & & \end{bmatrix} \cdot \begin{bmatrix} \langle I_{13}^{\pm} \rangle \\ \langle I_{24}^{\pm} \rangle \\ \langle S_{12}^{\pm} \rangle \\ \langle S_{34}^{\pm} \rangle \\ \langle DQ^{\pm} \rangle \\ \langle ZQ^{\pm} \rangle \end{bmatrix} \quad (1)$$

ω_{ik} are the frequencies of individual transitions in the IS spin system, and R_{ik} are the associated transverse relaxation rates (Figure 1). DQ stands for double-quantum transition, and ZQ for zero-quantum transition. With the assumption that the CSA tensor is axially symmetric, the relaxation rates R_{ik} are

$$R_{13}^I = (p^2 + 2f_I p \delta_I + \delta_I^2) \cdot 4J(0) \quad (2a)$$

$$R_{24}^I = (p^2 - 2f_I p \delta_I + \delta_I^2) \cdot 4J(0) \quad (2b)$$

$$R_{12}^S = (p^2 + 2f_S p \delta_S + \delta_S^2) \cdot 4J(0) \quad (2c)$$

$$R_{34}^S = (p^2 - 2f_S p \delta_S + \delta_S^2) \cdot 4J(0) \quad (2d)$$

$$R^{DQ} = (\delta_I^2 + 2f_c \delta_I \delta_S + \delta_S^2) \cdot 4J(0) \quad (2e)$$

$$R^{ZQ} = (\delta_I^2 - 2f_c \delta_I \delta_S + \delta_S^2) \cdot 4J(0) \quad (2f)$$

In equation (2), p is the dipolar interaction energy,

$$p = \frac{u_0 h \gamma_I \gamma_S}{16\pi^2 \sqrt{2} r_{IS}^3} \quad (3)$$

δ_S the ^{15}N -chemical shift anisotropy interaction,

$$\delta_S = \frac{\gamma_S B_o \Delta \sigma_S}{3\sqrt{2}} \quad (4)$$

and δ_I the ^1H -chemical shift anisotropy interaction,

$$\delta_I = \frac{\gamma_I B_o \Delta \sigma_I}{3\sqrt{2}} \quad (5)$$

The factor f_i accounts for the angular dependence of cross correlated relaxation effects, with

$$f_i = \frac{3 \cos^2 \Theta_i - 1}{2} \quad (6)$$

For dipole–dipole coupling/CSA cross correlation, Θ_i is the angle between the principal axis of the axially symmetric CSA tensor and the chemical bond linking the spins I and S (in equation (6), $i = S$ or I ; see equation (2)). For CSA/CSA cross correlation, Θ_i is the angle between the two CSA tensor principal axes (in equation (6), $i = c$; see equation (2)). For isotropically tumbling spherical structures the spectral density function at zero frequency is given by

$$J(0) = \frac{2\tau_c}{5} \quad (7)$$

where τ_c is the rotational correlation time of the molecule.

Equation (2) shows that for non-vanishing CSA values the single-quantum transitions, which represent the two fine

structure components of the I and S doublets, have different relaxation rates. Since p is field-independent and the CSA interaction increases in proportion to the field strength, there is a ‘magic field’ for one of the doublet components where its relaxation rate will be near zero, whereas the other component deteriorates due to rapid relaxation. For ^{15}N in peptide ^{15}N – ^1H groups one approaches this situation at the highest presently available ^1H frequencies of 900 MHz, and for the amide proton a minimal transverse relaxation rate is expected near 1000 MHz.^{5,7} For the zero-quantum and double-quantum transitions a different mechanism is responsible for the different relaxation rates of the individual fine structure components, i.e., cross correlation between the CSAs of the I and S spins [equations (2e) and (2f)]. This effect has been exploited for relaxation optimization in the three-dimensional NOESY- $[^1\text{H}, ^{15}\text{N}, ^1\text{H}]$ -ZQ-TROSY experiment.¹¹

For the practice of TROSY-NMR, one should keep in mind that some leakage is anticipated even for the ‘magic field condition’ of complete quenching of the transverse relaxation for an isolated two-spin system. Most important, relaxation of the spins in ^{15}N – ^1H moieties by dipole–dipole coupling with ‘remote’ protons, i.e., all protons outside of the ^{15}N – ^1H group, is the same for conventional NMR and for TROSY. This effect is minimized in uniformly deuterated proteins, where remote couplings are limited to other amide protons. For ^{15}N – ^1H groups the relative contributions from remote dipolar couplings to the overall transverse relaxation rates of the two spins are widely different. ^{15}N relaxation is dominated by the CSA of ^{15}N and the dipole–dipole interactions with the directly attached proton even in protonated proteins, but ^1H transverse relaxation is significantly enhanced by dipole–dipole interactions with remote protons, H_k , at distances r_k from the amide proton, as given by

$$R_L = \sum_{k=1}^n 5p_k^2 \cdot J(0) \quad (8)$$

with

$$p_k = \frac{u_0 h \gamma_H^2}{16\pi^2 \sqrt{2} r_k^3} \quad (9)$$

The overall relaxation rates for the individual multiplet components are obtained by addition of R_L (equation (8)) to one of the rates given in equations (2a), (2b), (2e) or (2f).⁷ In addition to remote dipolar couplings, deviations of the CSA tensors from axial symmetry and variable spatial orientations of the CSA tensors relative to the molecular structure may prevent the ideal ‘magic field condition’ for a given two-spin moiety, and cause the individual ^{15}N – ^1H groups in a protein to get closest to the ‘magic field condition’ at slightly different polarizing magnetic fields B_o .

2.2 Experimental Implementation of TROSY

Essential features of successful TROSY implementations are that the multiplet fine structure of the IS moieties is not decoupled, and that the desired slowly relaxing component, i.e., the one with the relaxation rates R_{13}^I and R_{12}^S [see Figure 1 and equation (2); note in equation (2) that for $I = ^1\text{H}$ and $S = ^{15}\text{N}$, p is a negative value], can be selectively detected with high sensitivity. A simple scheme for the application

Figure 2 Experimental schemes for three TROSY-type NMR experiments: (a) [^{15}N , ^1H]-TROSY correlation experiment; (b) ct-[^{13}C , ^1H]-TROSY correlation experiment; (c) [^{15}N , ^1H]-TROSY-HNCA triple resonance experiment. On the lines marked ^1H , ^{13}C and ^{15}N , narrow and wide bars stand for non-selective 90° and 180° radio-frequency pulses, respectively. In (a) and (c), the water magnetization along the $+z$ -axis during the entire experiment, using the water-selective 90° rf-pulses indicated by curved shapes on the line ^1H .⁹ The phases of the pulses are set to x unless indicated otherwise above the pulse. In (a) and (c), the ^{15}N evolution period is marked t_1 , in (b) the ^{13}C evolution period is t_1 , in (c) the ^{13}C evolution period is t_2 , and in all experiments the ^1H detection period is represented by a triangle. The line marked PFG indicates the pulsed magnetic field gradients applied along the z -axis. On the lines ^{13}C in (b), and ^{13}CO and ^2H in (c), the horizontal bars marked 'dec.' indicate periods of broadband decoupling. In (a), the time period τ is set to 2.7 ms; the phases for the pulses are $\psi_1 = \{y, -x\}$, $\psi_2 = \{-y\}$, $\psi_3 = \{y\}$, $\psi_4 = \{-y\}$, $\psi_5(\text{receiver}) = \{y, -x\}$, and a complex interferogram is obtained by recording a second FID for each t_1 delay, with $\psi_1 = \{y, x\}$, $\psi_2 = \{y\}$, $\psi_3 = \{-y\}$, $\psi_4 = \{y\}$. In (b), $\tau = 1.6$ ms, $T = 17.6$ ms; the phases for the pulses are $\psi_1 = \{-y\}$, $\psi_2 = \{\pi/4, 5\pi/4\}$, $\psi_3 = \{x, -x, -x, -x\}$, $\psi_4 = \{x, -x, -x, x\}$. A phase-sensitive spectrum in the t_1 dimension is obtained as described in Ref.¹² In (c), $\tau = 2.7$ ms, $T = 22$ ms; the phases for the pulses are $\psi_1 = \{x, x, -x, -x\}$, $\psi_2 = \{y, -y, -x, x\}$, $\psi_3 = \{y\}$; $\psi_4 = \{y\}$, $\psi_5 = \{y, -y, -x, x, -y, y, x, -x\}$. A phase-sensitive spectrum in the indirect dimensions is obtained as described in Ref.⁴⁵

of the TROSY principle is the single-quantum ^{15}N - ^1H correlation experiment (Figure 2a). For brevity we refer to this experiment as two-dimensional [^{15}N , ^1H]-TROSY.¹² There is no heteronuclear decoupling in the scheme of Figure 2(a), so that the transitions with different relaxation rates (Figure 1) are not mixed. The phase cycling, the pulsed field gradients and the

additional pulse on ^{15}N immediately before acquisition ensure that only the most slow relaxing transition in a ^{15}N - ^1H moiety is retained. The effects on the appearance of the spectrum are illustrated in Figure 3.¹⁰ In the conventional two-dimensional [^{15}N , ^1H]-COSY experiment,¹³ decoupling of ^{15}N and ^1H during the evolution and detection periods, respectively, leads to

Figure 3 Contour plots and cross sections of a backbone amide ^{15}N – ^1H correlation cross peak (see also Figure 1) obtained from three different types of ^{15}N – ^1H correlation experiments. The data was recorded with the uniformly ^{15}N -labeled protein *fushi tarazu* homeodomain in an 18 kDa complex with unlabeled DNA, solvent 95% H_2O /5% D_2O , $T = 4^\circ\text{C}$, $\text{pH} = 6.0$, ^1H frequency = 750 MHz. (a) Conventional broadband-decoupled ^{15}N , ^1H -COSY spectrum. (b) Same as (a) without decoupling during the evolution and detection periods. (c) ^{15}N , ^1H -TROSY recorded with the scheme of Figure 2(a). The arrows in the contour plots indicate the positions of the cross sections displayed in the bottom panels. The figure visualizes why corresponding peaks in COSY and TROSY spectra are displaced by 0.5^1J_{IS} (ca. 45 Hz for ^{15}N – ^1H) along both frequency axes. (Adapted from Ref.¹⁰)

observation of a single correlation peak per ^{15}N – ^1H moiety (Figure 3a). If the same spectrum is recorded without decoupling, a four-line fine structure is observed where the individual components have largely different linewidths (Figure 3b). Only the narrowest one of these four lines is observed in ^{15}N , ^1H -TROSY (Figure 3c).

The anticipated sensitivity loss due to retaining only one of the four multiplet components in ^{15}N , ^1H -TROSY can be largely made up by the use of new polarization transfer elements. In the scheme of Figure 2(a), the ST2-PT element is used before data acquisition, which retains 50% rather than only 25% of the original proton polarization.¹² Furthermore, in the absence of decoupling the steady-state

heteronuclear magnetization can be used in addition to the proton polarization.^{12,14} Overall, when working with structure sizes above 20 kDa, a superior ratio of peak height to noise is thus typically achieved with TROSY when compared with the corresponding conventional experiments (see Section 3).

3 TROSY IN NMR EXPERIMENTS WITH BIOLOGICAL MACROMOLECULES

3.1 TROSY in ^{15}N – ^1H Correlation Experiments

The Figure 4(a) shows a two-dimensional ^{15}N , ^1H -TROSY spectrum measured with the experimental scheme

Figure 4 Comparison of conventional and TROSY-type ^{15}N - ^1H correlation spectra recorded with the 110 kDa protein DHNA (same sample as in Figure 1). (a) Contour plot of ^{15}N - ^1H -TROSY; (b) Contour plot of single-quantum ^{15}N - ^1H -COSY; (c) and (d) Cross sections along $\omega_2(^1\text{H})$ and $\omega_1(^{15}\text{N})$, respectively, through the three peaks identified in the contour plots with an arrow, the amino acid symbol and the sequence position. In the cross sections one readily observes that corresponding peaks in ^{15}N - ^1H -COSY and ^{15}N - ^1H -TROSY spectra are displaced along both frequency axes by about 45 Hz (see Figure 3)

of Figure 2(a) for the 110 kDa homo-octameric protein DHNA (see legend to Figure 1). The gain in spectral resolution is readily apparent from comparison with the corresponding conventional two-dimensional ^{15}N - ^1H -COSY experiment (Figure 4b). Two-dimensional ^{15}N - ^1H -TROSY experiments can provide a ‘fingerprint’ for proteins in severalfold larger structures than with conventional NMR.¹⁵ The ^{15}N - ^1H fingerprint is highly sensitive to changes in the protein environment and thus presents a many-parameter NMR probe for studies of intermolecular interactions. For example, chemical shift mapping of the amide groups is used in SAR by NMR (SAR stands for ‘structure-activity relationship’),¹⁶ which is a screening method for high-affinity ligands of macromolecular receptors. With the use of two-dimensional ^{15}N - ^1H -TROSY this approach will now be applicable for much bigger receptor molecules, with molecular weights of the order of 100 kDa. Similarly, comparison of the fingerprints of individual proteins in the free state and incorporated in supramolecular structures enables the mapping of intermolecular contacts with these proteins in the higher-order structures.¹⁷ The introduction of the TROSY technique thus opens a wide range of new applications for solution

NMR, in particular also in the newly emerging field of functional genomics.

3.2 TROSY in ^{13}C - ^1H Correlation Experiments

The TROSY principle is not limited to ^{15}N - ^1H groups, but may be effective in a variety of multi-spin systems with cross correlated relaxation effects. As an illustration, we present here a constant-time ^{13}C - ^1H correlation experiment with aromatic rings of a protein, which can also be applied with ring ^{13}C - ^1H moieties of DNA and RNA. The spectrum of Figure 5 was obtained with the experiment of Figure 2(b). Since the aromatic protons have very small CSA, TROSY is used only in the ^{13}C dimension and the experiment includes decoupling during acquisition. In this constant-time experiment, TROSY does not affect the line shape but improves the sensitivity.¹⁴ Figure 5 shows that a four- to ten-fold signal enhancement was achieved for individual resonances of the aromatic rings in an experiment with a protein of molecular weight 16 kDa, and similar signal enhancements have been obtained for RNA and DNA molecules.^{18,19} For aromatic

^{13}C – ^1H groups the ‘magic field’ is approached near a ^1H frequency of 600 MHz, and applications of [^{13}C , ^1H]-TROSY are of interest for ^{13}C -labeled proteins and nucleic acids of all sizes.

3.3 TROSY for Observation of Scalar Couplings Across Hydrogen Bonds

Hydrogen bonds are key elements for the architecture of three-dimensional structures of proteins and nucleic acids as well as for intermolecular recognition. Their presence in biological macromolecules is usually only indirectly inferred from experimental data.²⁰ The improved spectral resolution achieved with TROSY now enables observation of scalar couplings across hydrogen bonds in nucleic acids as well as in proteins.^{21–24} As an illustration, Figure 6 shows a [^{15}N , ^1H]-TROSY correlation experiment recorded with high resolution along the $\omega_1(^{15}\text{N})$ dimension for the determination of scalar couplings across hydrogen bonds in Watson-Crick base pairs. Such data can be obtained using transverse relaxation optimization during a long ^{15}N evolution period, thereby accepting low sensitivity in order to achieve high resolution along the ‘indirect’ heavy-atom frequency axis. The $^hJ_{\text{NN}}$ couplings seen in Figure 6 are in the range 3–7 Hz; for smaller couplings across hydrogen bonds, more refined observation schemes are available.²⁴

Figure 5 Comparison of two different ^1H – ^{13}C correlation experiments recorded with the uniformly ^{13}C -labeled 16 kDa protein cyclophilin A. In the NMR sample the protein concentration was 1 mM, solvent D_2O , $\text{pD} = 6.5$, $T = 10^\circ\text{C}$, ^1H frequency 750 MHz. The spectral region shown contains aromatic resonances. (a) Two-dimensional ct-[^{13}C , ^1H]-COSY; (b) Two-dimensional ct-[^{13}C , ^1H]-TROSY, recorded using the pulse scheme of Figure 2(b). Corresponding peak positions in the spectra (a) and (b) differ by about 80 Hz along $\omega_1(^{13}\text{C})$, as indicated by the horizontal broken lines, which also identify the locations of the cross sections along ω_2 that are shown in the bottom panels. The assignments of selected cross-peaks are indicated. (Adapted from Ref.¹⁴)

Figure 6 NMR observation of scalar ^{15}N – ^{15}N couplings across hydrogen bonds in DNA. The definitions of the scalar couplings $^hJ_{\text{NN}}$ and $^hJ_{\text{HN}}$ in Watson-Crick base pairs are shown at the top. Cross sections were taken along the $\omega_1(^{15}\text{N})$ dimension through the individual cross peaks of the thymine imino ^{15}N – ^1H moieties in a [^{15}N , ^1H]-TROSY spectrum of a uniformly ^{13}C , ^{15}N -labeled 14-base pair DNA duplex. The splitting of the resonance lines manifests scalar couplings $^hJ_{\text{NN}}$ of about 6 Hz across the Watson-Crick hydrogen bonds. The nucleotides are numbered in the 5′-to-3′ direction for both strands. (Adapted from Ref.²²)

3.4 TROSY in Triple Resonance Experiments for NMR Assignments in Large Structures

The assignment of the chemical shifts to individual nuclei is indispensable as a basis for detailed studies of either molecular structure or intermolecular interactions, and most of the information contained in NMR spectra can only be extracted and exploited on the basis of individual resonance assignments.¹⁵ Once high-quality spectra became available with TROSY, it was therefore of keen interest to develop NMR techniques that can provide resonance assignments for large proteins. Both, assignment by sequential NOEs with ^2H , ^{15}N - or ^{15}N -labeled proteins and by triple resonance experiments with ^2H , ^{13}C , ^{15}N - or ^{13}C , ^{15}N -labeled proteins appear to be amenable to this task,^{9,15,25} but most of the work so far was done on the adaptation of triple resonance experiments for assignments in large molecules. In these experiments magnetization is transferred between $^1\text{H}^{\text{N}}$, ^{15}N and ^{13}C . Without the use of TROSY they have been routinely applied with structures of size 15 to about 30 kDa.

Figure 7 Impact of TROSY on the sequential resonance assignment of the polypeptide backbone in the 110 kDa protein DHNA (same sample as in Figure 1) using the HNCA triple resonance experiment of Figure 2(c). (a) The HNCA experiment correlates the ^1H and ^{15}N chemical shifts of a given amide ^{15}N – ^1H group with the $^{13}\text{C}^\alpha$ chemical shifts of the same residue, i, and the preceding residue, s, as indicated here by gray shading of the intraresidual and sequential transfer pathways. (b) and (d) Three-dimensional ^{15}N , ^1H]-TROSY-HNCA spectrum.⁴⁶ (c) and (e) Conventional three-dimensional HNCA spectrum. (b) and (c) show strips taken along the $\omega_2(^{13}\text{C})$ dimension at the ^1H and ^{15}N resonance frequencies of the residue indicated at the top of the strip. The width of the strips along the ^1H -dimension is 130 Hz. (d) and (e) are one-dimensional cross sections along the $\omega_2(^{13}\text{C})$ axis through the peaks in these strips. The dotted line in (b) indicates the sequential assignment pathway for the polypeptide segment 14–19, where the intraresidual and sequential cross peaks are identified with ‘i’ and ‘s’, respectively (see (a)). The highly flexible C-terminal Lys 121 is the only residue that was observed in both spectra, and it is added here as an internal reference for this experiment (see text). (Adapted from Ref.²⁸)

In triple-resonance experiments with large proteins the implementation of TROSY prevents fast transverse relaxation of ^{15}N during the extended time periods with transverse ^{15}N magnetization that are needed for polarization transfers and ^{15}N evolution, and reduces the transverse ^1H relaxation rate during the acquisition of the amide proton signal.²⁶ This is illustrated here with the HNCA experiment. The magnetization transfer pathway is indicated in Figure 7(a), and an experimental scheme is shown in Figure 2(c). Since the triple resonance experiments of interest usually contain a 'constant-time evolution period' for ^{15}N ,^{9,27} implementation of TROSY does not affect the ^{15}N line shape but yields important gains in sensitivity, which are dependent on the size of the molecule studied. The use of TROSY in triple resonance experiments has enabled backbone assignments for proteins in large structures, such as the 110 kDa ^2H , ^{13}C , ^{15}N -labeled octameric protein DHNA.²⁸ For this structure, TROSY yielded 20- to 50-fold signal enhancements for individual residues in the structured segments of the polypeptide chain, and only the highly flexible C-terminal residue Lys 121 gave comparable results with and without TROSY (Figure 7).

With TROSY-type triple resonance experiments, sequential assignments can now routinely be obtained for proteins in structures with molecular weights of 100 000 and beyond. On top of this 'basic TROSY effect' the modified triple resonance experiments can be further optimized, for example, for improved spectral resolution through the use of ^{13}C constant-time evolution,²⁹ or for further optimization of the sensitivity with the introduction of one of a variety of sensitivity enhancement schemes, which have in part also been used for [^{15}N , ^1H]-TROSY and [^{13}C , ^1H]-TROSY.⁷

4 NEW STABLE ISOTOPE LABELING STRATEGIES FOR TROSY NMR WITH LARGE STRUCTURES

With TROSY enabling the recording of high-quality solution NMR spectra of large structures, one can anticipate being faced with highly complex NMR spectra. Actually, many large systems give spectra of manageable complexity. Examples are uniformly labeled oligomeric proteins with high internal symmetry, and isotope-labeled proteins in complexes with unlabeled nucleic acids or unlabeled lipids and detergents. In contrast, uniformly labeled proteins without internal symmetry show increasing complexity of the NMR spectrum with increasing size. As a response to this challenge there are now already new biochemical approaches available for reducing the spectral complexity to a manageable level even for large proteins, using segmental isotope labeling.^{30–33}

Segmental isotope labeling for protein NMR has been achieved using either transplicing or chemical ligation to assemble proteins from two or more independently generated polypeptide fragments, which are separately produced in bacteria and can thus be obtained with and without isotope labeling. The solution structure of the labeled domain can then be studied by NMR without interference from NMR lines originating from the other domains. By repetition of the NMR experiments using different protein preparations with isotope labeling of different individual domains, the intact protein can become accessible for detailed studies by TROSY-NMR, although it would, because of its large size

produce overcrowded NMR spectra if uniform isotope labeling were used.

5 COMBINING TROSY WITH CROSS CORRELATED RELAXATION-INDUCED POLARIZATION TRANSFER FOR STUDIES OF VERY LARGE STRUCTURES

In the common heteronuclear NMR experiments, magnetization is transferred between the different types of nuclei via scalar spin–spin couplings, using INEPT transfers.^{9,34} With TROSY being applied only during the evolution and detection periods (Figure 2), rapid transverse relaxation during the INEPT transfers becomes a limiting factor for structures with molecular weights above approximately 100–150 kDa. Cross correlated relaxation-enhanced polarization transfer (CRINEPT) overcomes this limitation by combining INEPT with cross-correlated relaxation-induced polarization transfer (CRIPT).^{35,36} The transfer efficiency of CRIPT increases proportional to the size of the molecule, so that it becomes a highly efficient transfer mechanism for structure sizes above 200 kDa in aqueous solution. Compared to combining INEPT with the use of TROSY during the evolution and acquisition periods (Figure 2), substitution of INEPT by CRINEPT can thus yield a further significant gain in sensitivity when studying very large structures. In addition to the improved transfer efficiency, the combination of TROSY and CRINEPT results in an experiment with transverse relaxation optimization throughout the entire pulse sequence. In practice, CRINEPT has so far mainly been used in ^{15}N – ^1H -correlation experiments,⁸ and high quality fingerprints have been recorded for structures with molecular weights up to 900 kDa.

6 CONCLUSIONS AND OUTLOOK

The most immediate applications of the potentialities of TROSY and CRINEPT are based on observing fingerprints of proteins in ^{15}N – ^1H -correlation spectra recorded for structures with mass up to 100 kDa and beyond (Figure 4), for which sequence-specific NMR assignments can be obtained (Figure 7). Practical use for studies of intermolecular interactions in supramolecular assemblies has been described,^{17,37} and the way is open for acquiring structure–activity relationship data with large receptor molecules.³⁸ TROSY-based NOESY experiments for the collection of structural constraints should enable three-dimensional solution structure determination of proteins larger than 50 kDa,^{11,39,40} if segmental labeling is also applied. An exciting immediate prospect are structure determination and further physical-chemical and functional characterization of small membrane proteins reconstituted in water-soluble detergent or lipid micelles, which may then have overall molecular weights of the order 100 kDa.^{41–43} Further exploration of the potentialities of TROSY and CRINEPT will be supported by future refinement of isotope labeling techniques for proteins and nucleic acids, the use of spectrometers operating at 900 MHz and beyond, and other advances in NMR techniques.⁵

1 INTRODUCTION

The use of precursors labeled with stable isotopes, especially ^{13}C and ^{15}N , in biosynthetic feeding experiments with subsequent analysis of the biosynthesized compounds by high-field NMR spectroscopy has become one of the most powerful tools for studying natural product biosynthesis. The NMR method provides information about the location or distribution of the isotope in the metabolite and, by analysis of homonuclear or heteronuclear coupling patterns, can reveal information about metabolic pathways or the nature of bond-forming reactions.

An important prerequisite for the use of NMR in biosynthesis studies is the unequivocal assignment of all proton, carbon, and nitrogen resonances in the target molecule. After recording ^1H and broadband proton-decoupled ^{13}C NMR spectra, the most common 2D NMR techniques employed are: COSY¹ (to determine all proton–proton correlations); DEPT² (to determine the multiplicity of carbon atoms or nitrogen atoms); HETCOR³ and HMQC⁴ (to determine which protons are attached to specific carbons or nitrogens); COLOC⁵ and HMBC⁶ (to determine long-range couplings to assign quaternary carbons or nitrogens and correlations between different partial structures which are essential to assemble the molecule). The advent of inverse detection techniques such as HMQC and HMBC has greatly facilitated the assignment of ^{15}N resonances.

2 LABELING WITH ^{13}C

2.1 Singly Labeled Precursors

Carbon-13 NMR spectroscopy was first reported in the 1950s and applied to biosynthetic studies almost two decades later. In the early days, ^1H NMR was used to detect the ^1H – ^{13}C coupling due to the isotopically enriched carbon nuclei, a method which usually did not give information about

quaternary carbons and was therefore limited in its application. The disadvantages of ^{13}C NMR, low natural abundance (1.1%) and a small magnetogyric ratio ($\gamma = 6.72 \times 10^7$), resulting in low sensitivity (^{13}C resonances are about 6000 times less sensitive than ^1H resonances), were overcome by advances in instrumentation, especially the development of the pulse Fourier transform technique, which increased the sensitivity dramatically.⁷

Feeding a precursor with a single ^{13}C label allows the fate of the labeled atom to be traced through a metabolic sequence. In the ^{13}C NMR spectrum of the product, the enrichment is indicated by an increased intensity of the signal(s) corresponding to the atom or atoms that arise from the labeled atom of the precursor. Comparing integrals of singlets with integrals of multiplets which result with and without decoupling, respectively, is not a precise method. To allow a fairly accurate assessment of the incorporation, the ^{13}C NMR spectra of the unlabeled material and the biosynthesized product are normally acquired in the proton-decoupled, inverse-gated mode in order to obtain the decoupled signals without the NOE. Integration of the enriched signals in comparison to other signals in the spectrum and to the signal of the nonlabeled material correlates to the percentage of incorporation of the precursor into the product. Enrichments should be at least 0.5% ^{13}C above natural abundance to be unequivocally detectable. In cases of very high incorporation, the natural abundance signal will be small compared with the enriched signal, and for quantification purposes the rate of incorporation will be determined more precisely by integration of the ^{13}C satellites in the ^1H NMR spectrum. If the precursor is incorporated into multiple sites of the metabolite, either a carbon which does not derive from this precursor has to be chosen as a reference carbon or it is necessary to introduce an unlabeled carbon by derivatization.

The literature is replete with studies using this approach of feeding precursors carrying single ^{13}C labels. Particularly numerous are studies on the biosynthesis of various polyketide-derived natural products, as exemplified by the dimeric benzoisochromanquinone, actinorhodin (Figure 1).⁸ In this case, the labeling experiment also established the point of dimerization: the two carbon atoms 10 and 10', which appear as quaternary carbons, not the methine carbons 9 and 9', are derived from the methyl group of acetate.

In some experiments with whole cells, a precursor may not be incorporated due to its inability to penetrate the cell membrane. This is often the case with carboxylic acids, such as malonic acid or shikimic acid. Sometimes the problem can be overcome by feeding a derivative which can be cleaved inside the cell, e.g. diethyl malonate instead of the free acid.

Figure 1 Biosynthesis of actinorhodin

In other cases where a precursor does not penetrate to the site of synthesis, evidence for its involvement may be attained indirectly. An example is the biosynthesis of the antibiotic asukamycin,⁹ where ^{13}C -labeled shikimic acid gave only very poor incorporation. However, feeding a more general precursor such as $[\text{U-}^{13}\text{C}_3]\text{glycerol}$ resulted in the expected shikimate-type labeling pattern for the isolated asukamycin. The ^{13}C NMR spectrum showed the presence of two doubly coupled spin systems (C-7'/C-8'/C-9', C-11'/C-12'/C-13') and a single, enriched, noncoupled signal for C-10', indicating that all seven carbon atoms of this moiety derive directly from shikimate, not via aromatic amino acids. In other instances of impermeability of cell membranes to specific precursors, e.g. phosphate esters, information may only become available from in vivo studies with cell-free systems or purified enzymes where the precursor will always be able to reach the site of synthesis. Many studies in carbohydrate metabolism fall into this category. For example, the definitive proof for a rearrangement of ribulose 5-phosphate into a tetrulose 4-phosphate in riboflavin biosynthesis¹⁰ required the use of various ^{13}C -labeled ribulose 5-phosphates in a cell-free system from the riboflavin producer *Candida guilliermondii*.

2.2 Multiply ^{13}C -Labeled Precursors

In contrast to experiments with singly labeled precursors where the fate of atoms is explored, in the case of multiply labeled precursors the fate of bonds can be followed through a metabolic reaction sequence. If the doubly labeled precursor in which the ^{13}C atoms are adjacent is incorporated intact, the ^{13}C NMR signal of each labeled carbon atom is split into a doublet due to coupling to the neighboring ^{13}C atom. Since one-bond carbon-carbon couplings are much larger (–20 to 200 Hz) than two- or three-bond couplings (0–16 Hz), adjacent labeled carbon atoms are easy to detect in the ^{13}C NMR spectra. The administered precursor is diluted with unlabeled material which is either formed in the biological system from unlabeled nutrients or is added externally together with the labeled sample. If the bond between the two enriched carbons is broken during the metabolic conversion, the stable isotope at each terminus will be diluted with a large amount of ^{12}C . Thus the probability of reconnecting two ^{13}C nuclei in the same molecule again becomes very low. If the coupling is retained in the product, the two nuclei must have originated from the same molecule, therefore suggesting that the bond between them has never been broken.

A major advantage of this approach is the increase of detection sensitivity in cases of low incorporation, a common problem in higher plants. The reason is that intact incorporation of the precursor now gives rise to new signals, the coupled satellites, rather than a small increase in existing natural abundance signals. This was neatly demonstrated in the biosynthesis of the alkaloid anabesine from $[\text{4,5-}^{13}\text{C}_2]\text{lysine}$ in *Nicotiana glauca* (Figure 2).¹¹ The resulting anabesine showed the presence of contiguous ^{13}C atoms at C-4' and C-5'. The coupled carbons have very similar chemical shifts (δ 25.87 and 25.37) and therefore only the inner satellites [$J(\text{C-4}', \text{C-5}') = 33 \text{ Hz}$] could be observed. The specific incorporation was calculated from the intensities of these inner satellites as 0.25%.

Figure 2 Detail of the ^{13}C NMR spectrum of anabesine derived from $[\text{4,5-}^{13}\text{C}_2]\text{lysine}$ at the enriched C-4' and C-5' positions

The bond-labeling approach is used extensively to evaluate the mode of incorporation of precursors into more complex products, for example the way a polyketide chain folds to cyclize into a polycyclic aromatic system. The pioneering study demonstrating the utility of this approach was carried out by Seto and co-workers,¹² and followed the incorporation of $[\text{1,2-}^{13}\text{C}]\text{acetate}$ into the polyketide mollisin, a metabolite of *Mollisia caesia*. The intact incorporation of six pairs of carbons from acetate allowed the authors to derive a pathway other than the two which were originally proposed. A limitation in the application of this methodology to more complex precursors is the labor and cost involved in the synthesis of the requisite labeled compounds, if they are not commercially available. Bond labeling is also widely used in combinations of ^{13}C with other nuclei to probe for intact incorporation of ^{13}C – ^{18}O or ^{13}C – ^2H bonds (i.e. for retention of these heteroatoms on the carbon framework), but detailed discussions of this topic would go beyond the scope of this article.

Multiple labeling can also be used to probe for the occurrence of rearrangement reactions in which new carbon-carbon connectivities are established, and whether such reactions are intra- or intermolecular. A rearrangement of tryptophan was postulated to account for the formation of an unusual indolic acid moiety in the biosynthesis of the thiopeptide antibiotic nosiheptide (Figure 3).¹³ In the proposed reaction the carboxyl group of tryptophan would be connected to C-2 of the indole ring, while the α -carbon and the amino group of the tryptophan side chain are removed and the methylene carbon is converted into a methyl group. This was probed by preparing and feeding $[\text{carboxyl, indole-2-}^{13}\text{C}_2]\text{tryptophan}$. The ^{13}C NMR spectrum of the resulting nosiheptide showed a one-bond coupling of 75.5 Hz between the Ind-CO and Ind-C-2 resonances, proving that this unusual rearrangement of tryptophan does take place and that it is a strictly intramolecular process.

Figure 3 Formation of the indolic acid moiety of nosiheptide from tryptophan

Figure 4 Incorporation of [2,11- $^{13}\text{C}_2$]porphobilinogen into uroporphyrinogen-III

A classic example of multiple labeling, in this case in nonadjacent positions, to probe for a rearrangement reaction can be found in porphyrin biosynthesis. [2,11- $^{13}\text{C}_2$]Porphobilinogen (one part labeled and four parts unlabeled material to ensure dilution) was converted with an enzyme preparation into uroporphyrinogen-III.¹⁴ The ^{13}C NMR spectrum revealed the unique labeling and coupling pattern shown in Figure 4, proving that the enzyme assembles four intact units of porphobilinogen, but inverts one of these units to generate the type III substitution pattern.

Uniformly ^{13}C -labeled precursors such as glucose or glycerol are useful for mapping unknown metabolic pathways. Detailed analysis of the resulting ^{13}C - ^{13}C coupling patterns can reveal which major metabolic pathways provide the various components of the product molecule. The complexity of these coupling patterns necessitated the development of techniques such as ^{13}C COSY and double quantum coherence NMR (e.g. 2D INADEQUATE). The ^{13}C COSY technique was employed in a biosynthetic study of the *Klebsiella* K3 serotype polysaccharide using [U- $^{13}\text{C}_6$]glucose as a precursor.¹⁵ Due to the appearance of additional multiplets within the cross peaks, ^{13}C COSY spectra are quite different from ^1H COSY spectra. The observed cross peaks are a combination of superimposed responses from molecules with different patterns of ^{13}C labeling. These additional peak components are attributable to substrate catabolism which results in ^{13}C loss at various sites. It was shown that the major biosynthetic pathway for polysaccharide formation proceeds via intact incorporation of the hexose unit into the polysaccharide and that 30% of the glucose substrate is catabolized prior to incorporation into the polysaccharide, almost exclusively via the phosphogluconate pathway.

In the case of the antibiotic reductionmycin¹⁶ the question was whether one part of the molecule was derived from a shikimate pathway. The broadband decoupled ^{13}C NMR spectrum of the antibiotic labeled from [U- $^{13}\text{C}_3$]glycerol indicated extensive enrichment and coupling throughout the molecule. A doubly coupled assembly of three carbon atoms (C-3''/C-4'/C-5') indicated intact incorporation of a glycerol unit. However, the C-4' signal displayed an eight line pattern

Figure 5 Labeling and ^{13}C - ^{13}C coupling pattern in the dihydrofuranylacrylic acid moiety of reductionmycin from [U- $^{13}\text{C}_3$]glycerol

instead of the expected four lines, implying the presence of another coupled two- or three-bond system involving C-3'. A 2D INADEQUATE experiment clearly revealed that C-3' was coupled to both C-2' and C-4' with a coincident coupling of 41 Hz. In the contour projection, C-4' again showed an eight-line pattern, which would be expected for a superimposition of two arrays of three coupled carbons. The two possible arrangements of an intact three-carbon unit involving C-3' and C-4' were distinguished by spectral simulation with the Bruker PANIC program that calculated an excellent match for the superimposition of a C-3''/C-4'/C-5' and C-3'/C-4'/C-5' coupling pattern (Figure 5), pointing to formation from shikimate via a symmetrical intermediate.

Use of [U- $^{13}\text{C}_3$]glycerol (or [U- $^{13}\text{C}_3$]glucose) as a biosynthetic probe can result in very complex coupling patterns due to intact incorporation with coupling of all three involved carbon signals, intact incorporation of two of the three glycerol carbons or of only one of the labeled carbons. This scenario with doubly and singly coupled patterns will create difficulties in data interpretation, especially in larger molecules. A 2D INADEQUATE experiment identifying the doubly coupled species will not separate them from singly coupled patterns. By using a triple quantum version of a 2D INADEQUATE experiment,¹⁷ it is possible to observe selectively doubly coupled species in the presence of singly coupled species and determine their molecular connectivities. This was demonstrated in the biosynthesis of acarbose, an inhibitor of α -glucosidases. A strong signal indicated the presence of a contiguous array of three ^{13}C nuclei representing C-6, C-1, and C-2 of the valienamine moiety.

Inverse detection of ^{13}C multiple quantum coherence in biosynthetic studies¹⁸ was demonstrated for the first time in the biosynthesis of cycloheptanecarboxylic acid from [U- $^{13}\text{C}_6$]glucose in *Bacillus cycloheptanicus*. Cycloheptanecarboxylic acid serves as the starter unit to which five acetate units are added in the formation of ω -cycloheptyl fatty acids. Double and triple quantum INADEQUATE experiments were unsuccessful due to low sample concentrations. Glucose labels, as expected, the 10 chain carbons and also the cycloheptane ring with intact two- and four-carbon units. The four-carbon unit appears to be derived from a three- and a one-carbon unit of glucose (i.e., erythrose) and has a C_2 axis of symmetry. The coupling pattern pointed to an aromatic amino acid,

phenylalanine, as the proximate precursor. This inverse technique provides higher sensitivity because it uses fewer pulses and is therefore less susceptible to instrumental imperfections.

3 LABELING WITH ^{15}N

3.1 Direct Detection

Until recently, ^{15}N NMR was limited in its applications due to the low natural abundance of ^{15}N (0.37%). Its sensitivity is 0.2% compared with ^1H NMR and it requires longer relaxation times than ^{13}C NMR. Its negative magnetogyric ratio causes negative NOE and can consequently decrease or null out signals. Therefore, ^{15}N NMR spectra are usually acquired in the inverse-gated mode, which consumes more instrument time. Additionally, the ^{15}N chemical shifts are often very solvent-dependent. Nevertheless, there are numerous examples where direct detection of ^{15}N has been applied in biosynthetic studies of secondary metabolites¹⁹ and in biological systems.²⁰

Nitrogen-15 NMR spectroscopy has been used to study the conversion of L-lysine to D-lysine by *Neurospora crassa*.²¹ Analysis by mass spectrometry had shown that the ^{15}N label from L-[2- ^{15}N]lysine was lost, whereas the ^{15}N label from L-[6- ^{15}N]lysine had been retained. The ^{15}N NMR spectrum of D-lysine from the latter experiment revealed that the label was attached to C-2, suggesting that L-pipecolic acid is an intermediate in the conversion (Figure 6).

In a recent study, the origin of specific nitrogens in the highly modified peptide antibiotic nosiheptide (Figure 7) was investigated by ^{15}N NMR.²² Assignment of the ^{15}N signals to the 13 nitrogens in the molecule was accomplished by HMQC⁴ and HMBC⁶ techniques. Comparative analysis of samples enriched by feeding $^{15}\text{NH}_4\text{Cl}$, [^{15}N]glycine, and [^{15}N]glycine plus unlabeled serine revealed that the carboxy-terminal amide nitrogen in the antibiotic is derived specifically from another molecule of serine, whose carbon skeleton is removed in the process.

3.2 Indirect Detection of ^{15}N

Indirect detection of ^{15}N by ^{13}C NMR spectroscopy relies on the observation of carbon signals coupled to ^{15}N . Generally, one-, two-, and three-bond couplings are observed. Due to the negative magnetogyric ratio, the 3J and most of the 1J values are negative. In contrast to ^{13}C – ^1H coupling constants,

Figure 6 Interconversion of L- and D-lysine via L-pipecolic acid

Figure 7 Structure of nosiheptide

the ^{13}C – ^{15}N two-bond coupling can be larger than the one-bond coupling.²³ The coupling constants vary depending on the structure and are difficult to predict. Tables with numerous examples are given in the literature.²³

Various precursors containing ^{13}C and ^{15}N adjacent to each other, for example, [2- ^{13}C , ^{15}N]amino acids, have been incorporated into different metabolites with the ^{13}C – ^{15}N bond intact. In the biosynthesis of the potent anticancer agent streptonigrin,²⁴ it was shown that tryptophan is the precursor of the phenylpicolinic acid moiety (Figure 8). The first step is presumably the conversion to a β -carboline undergoing hydroxylation and ring cleavage. The site of ring cleavage was determined by feeding [2- ^{13}C ,1- ^{15}N]tryptophan to *Streptomyces flocculus* and analyzing the ^{13}C NMR spectrum of the isolated streptonigrin. The spin-coupled doublet flanking the C-5 natural abundance singlet clearly proved that the original indole nitrogen had been retained and that an unprecedented bond cleavage had occurred. Another interesting example is the formation of the isonitrile function in the biosynthesis of hapalindole A,²⁵ the major isonitrile in the terrestrial cyanophyte *Hapalosiphon fontinalis*. In the natural abundance ^{13}C NMR spectrum of hapalindole A, the isonitrile carbon signal is split into a broad triplet [$J(^{13}\text{C},^{14}\text{N}) = 4\text{ Hz}$]. The ^{13}C NMR spectrum of the material resulting

Figure 8 Biosynthesis of streptonigrin from [2- ^{13}C ,1- ^{15}N]tryptophan

Figure 9 1,2 migration of an amino group of lysine in the biosynthesis of streptothricin F

from feeding $[2\text{-}^{13}\text{C}, ^{15}\text{N}]$ glycine showed a 100% enhancement of the isonitrile carbon signal at δ 157.9 (1% incorporation) and a sharp doublet [$J(^{13}\text{C}, ^{15}\text{N}) = 6\text{ Hz}$] superimposed onto the broad triplet. Therefore, the C-2–N assembly of glycine is incorporated intact into the isonitrile group, without significant loss of ^{15}N label due to transamination of the glycine prior to isonitrile formation.

As with multiple ^{13}C labeling, precursors carrying ^{13}C and ^{15}N in nonadjacent positions can be used to probe the nature of rearrangement reaction, by looking for the formation of a ^{13}C – ^{15}N bond in the product. An example for a 1,2 migration of a ^{15}N label is found in the biosynthesis of streptothricin F.²⁶ $[3\text{-}^{13}\text{C}, ^{15}\text{N}]$ Lysine was fed to *Streptomyces* L-1689-23; the ^{13}C NMR spectrum of the resulting antibiotic exhibited a doublet [$J(\text{CN}) = 3.4\text{ Hz}$] for C-16, proving that the original α -amino nitrogen had been retained but that it had migrated to C-3 in an intramolecular process (Figure 9).

1 INTRODUCTION

Many investigations of biosynthetic pathways rely on tracing the fate of one or more particular hydrogen atoms in a precursor when it is transformed into the final metabolite.¹ The approach is especially useful when investigating alternative pathways where one necessarily involves loss of a key hydrogen atom whereas the other allows its retention. More generally, labeling with a hydrogen isotope can also be used to demonstrate the incorporation of complete structural fragments of a precursor as long as the isotope is attached via a bond which is unlikely to be broken in the course of the proposed biosynthetic transformations.

Both isotopes of hydrogen, deuterium and tritium, have been used in this way, but deuterium has proved to be by far the more popular choice. The isotope can be detected in the final metabolite directly by mass spectrometry or ²H NMR or indirectly by the diminution of a proton signal in the ¹H NMR spectrum. The most effective method is unquestionably direct observation of the isotope by ²H NMR.

Deuterium is a quadrupole nucleus with spin 1. As a consequence of the low magnetogyric ratio (0.154), deuterium resonates at 61 MHz in a magnetic field of 9.4 T compared with 400 MHz for ¹H. The chemical shift values observed in ²H NMR spectra are closely similar to those of the equivalent protons, although the scale (in hertz) is only 15% that of the ¹H NMR spectra. Coupling constants $J(^2\text{H}, ^1\text{H})$ also approximate to one-sixth the value of $J(^1\text{H}, ^1\text{H})$. The close correspondence of ¹H and ²H NMR spectra is invaluable for biosynthetic studies, because assignments made using ¹H NMR techniques on unlabeled material can be extrapolated into the ²H NMR spectrum.

The relaxation behavior of deuterium is dominated by a quadrupolar mechanism and this results in extensive line broadening. This effect combined with the limited dispersion means that ²H NMR spectra are characterized by spectral crowding and poor resolution. Relaxation times are short, however, which, combined with the absence of a NOE effect, minimizes the possibility of partial saturation. This factor insures that the extent of enrichment in a partially deuterated molecule may be determined accurately by integration. Other advantages of using ²H NMR in biosynthetic study are firstly, that the isotope is an inexpensive tracer which, unlike tritium,

Scheme 1

is nonradioactive and does not require special handling; and, secondly, that the low natural abundance (0.016% compared with 1.1% for ¹³C) enables the incorporation of deuterium-labeled precursors to be positively identified (by a doubling in peak height over natural abundance) even after 6600-fold dilution of the precursor in the metabolic pool.

2 MECHANISTIC STUDIES

In a pioneering study in which L-[1-²H]cystine (1) was fed to the mold *Penicillium chrysogenum* it was shown by ²H NMR that all of the isotopic label incorporated was present at C-6 of the derived penicillin G (2).² An α,β -dehydrocysteine residue could thus be discounted as an intermediate in the biosynthetic transformations which lead from (1) to (2). This work provides a striking demonstration of the mechanistic use of deuterium labeling in that the positive incorporation rules out obligatory loss of the isotopic label at one of the steps in the biosynthetic pathway.

Another early study provided detailed mechanistic and stereochemical insights into the processes of griseofulvin (3) biosynthesis.³ The metabolite is biosynthesized by the head-to-tail linkage of seven acetate units, as indicated in Scheme 2. Following incorporation of CD₃CO₂H, four of the seven methyl derived sites, (3, 3', 5', and 7) gave rise to signals in the ²H NMR spectrum (the rest had been stripped of their hydrogen atoms). Significantly, only one of the two hydrogen atoms at C-5' was labeled (the α -position) showing that the second hydrogen atom was not derived from the CD₃ group of the precursor. The ²H NMR spectrum also showed weak signals from two O–Me groups, indicating that some of the deuterium of the acetate precursor had 'leaked' through incidental pathways of primary metabolism to enter the O-methyl groups. This study demonstrates a key advantage of

Scheme 2

Scheme 3

^2H NMR over mass spectrometry as an analytical technique in biosynthetic studies. ^2H NMR not only shows that deuterium is present in a nondestructive way, it also gives information as to how the isotope is distributed over the different labeled sites in the molecule. The observation of deuterium in the *O*-methyl groups emphasizes the need for caution in interpreting the results of deuterium isotopic incorporation studies. In a more recent example of a mechanistic study it was shown that H-5a of roquefortine (4) is derived from H-2 of tryptophan (5) (Scheme 3).⁴ The precursor was administered in multiply-labeled form with deuterium at all four sites in the carbocyclic ring as well as at the key site H-2 (the extra four deuterium atoms serve as an internal standard). An enriched $M + 5$ ion in the mass spectrum of the resulting metabolite established that all five deuterium atoms were retained. The ^2H NMR spectrum showed five enriched signals corresponding to the presence of deuterium at the indicated sites. The signal for deuterium at position 5a was well resolved even in the ^2H NMR spectrum, so the incorporation of deuterium at that site was established unambiguously. It is worth noting here that an earlier investigation using ^1H NMR to detect incorporation of ^2H at C-5a had failed to establish this point.

^2H NMR has also been used as an analytical tool for investigating biosynthetic pathways in plants, where dilution of the isotopic label is usually a more serious problem than in microorganisms. In one of many successful applications of the technique, the labeling patterns in (–)-anagurine (7) derived biosynthetically from (*R*)- and (*S*)-[1- ^2H]cadaverines, (5) and (6) respectively, were established (Scheme 4).⁵ A point of interest in this investigation was the danger of incorrectly assigning the enriched peaks in the metabolite because of the variability in the chemical shift depending on sample conditions. This was overcome by running the ^1H NMR spectrum as a control on each sample analysed by means of ^2H NMR.

In the same investigation the patterns of incorporation of (5) and (6) into the related alkaloid (+)-sparteine (8) were also established by using ^2H NMR. The close correspondence of the labeling patterns for (7) and (8) produced in these experiments (with the notable exception of C-6) supports the idea that (7) might be derived biosynthetically via (8). If so, the piperidone ring of (7) is likely to derive from ring D of (8). However, the epimerization at C-6 in this overall conversion without loss of deuterium presents a puzzling problem.

In an earlier study, the incorporation of (5) and (6) into (9), the enantiomer of (8), was also investigated by using ^2H NMR.⁶ Once again the complete labeling pattern could be assigned. Comparison of (8) and (9) reveals that rings A and D have the same stereochemical labeling pattern, but that the

Scheme 4

labels associated with the two central rings are opposite in configuration at equivalent sites. These results demonstrate the power of ^2H NMR spectroscopy for elucidating the stereochemistry as well as the sites of deuterium incorporation. Further examples of elegant mechanistic studies can be found in related studies of lupinine biosynthesis.⁷

The literature is rich in examples of the use of ^2H NMR to study mechanistic aspects of the biosynthesis of terpenes. Two examples are presented here, both of which were pioneering studies which excited great interest by demonstrating the power of this approach.

When the deuterated mevalonate (10) was incorporated into the microbial terpene ovalicin (11), five deuterium atoms were detected by ^2H NMR.⁸ The observed labeling pattern considerably narrowed the range of possible biosynthetic pathways.

In a subsequent study, chirally labeled mevalonates (12) and (13) were incorporated into the fungal terpene rosenonolactone (14) (Scheme 6).⁹ The ^2H NMR spectrum revealed that the two hydrogen atoms of the vinyl group in (14) are specifically derived from those at C-4 of mevalonate with the pro-(*R*) and pro-(*S*) hydrogen atoms destined to become (*Z*) and (*E*) hydrogen atoms, respectively. This evidence allowed

Scheme 5

Scheme 6

deductions to be made concerning the stereochemistry of the cyclization process in which ring C of the natural product is formed.

3 PRECURSOR-PRODUCT RELATIONSHIPS

The incorporation of advanced precursors has also been studied by ^2H NMR spectroscopy. In many such cases the aim is to use the ^2H label to trace the structure of the administered precursor as a whole, rather than probe the mechanism or stereochemistry of reactions involving hydrogen atoms at particular sites. There is then a greater choice of site of labeling, which is often dictated by the ease of synthesis of the precursor or the ease and reliability of determining the site of labeling in the product. As far as the latter point is concerned, signals arising from predicted sites of incorporation should be well resolved in the ^2H NMR spectrum.

In a recent example of this type of experiment the advanced precursor (15) was synthesized specifically labeled by deuterium (Scheme 7).¹⁰ Its specific incorporation into colletodiol (16) was established by ^2H NMR of the metabolite which showed a single enriched peak corresponding to the expected position C-4. No other deuterium-enriched peaks were observed, showing that biodegradation of the labeled precursor to produce other acceptable labeled precursors had not occurred to a significant extent. The site of label in this study was dictated mainly by synthetic considerations.

A second example involved a study of the biosynthesis of the ionophore antibiotic tetronasin (18) (Scheme 8).¹¹ Here the precursor (17) was labeled in separate experiments by deuterium at two alternative methyl groups as indicated. The acyl group (C-10) destined to be incorporated was derivatized

Scheme 7

Scheme 8

as a thioester to aid incorporation. The acyl chain of (17) is readily degraded by the organism to produce smaller labeled building blocks (CD_3 labeled acetate or propionate) acceptable to the biosynthetic pathway. Initially, degradation was the dominant fate of the precursor, and this resulted in the production of metabolite multiply labeled at many sites, a situation which was readily detected by ^2H NMR. Subsequently, conditions were found under which specific incorporation of the intact C-10 acyl residue occurred to give specifically labeled metabolite. The two labeled forms of (17) were fed in separate experiments to produce differently labeled forms of metabolite. From the positions of the ^2H NMR signals in the spectra of the metabolite it was evident that the two labeled methyl groups were specifically incorporated at the predicted sites confirming intact incorporation of the acyl residue. The choice of site of labeling in this study was dictated partly by NMR considerations (the signal for the CD_3 groups at C-26 and C-27 are completely resolved), but once again synthetic considerations were important. It will be apparent that the configurations at C-20, C-21, and C-22 of (18) match those of the equivalent sites of the precursor. Other labeled diastereoisomers of (17) were tested, but none resulted in a specific incorporation, showing that the stereochemistry of the precursor is retained.

4 CONCLUSIONS

The examples presented in this account represent but a small fraction of the successful applications of ^2H NMR in biosynthetic studies. Even when the efficiency of incorporation is very low, satisfactory spectra on the resulting labeled metabolite can be acquired by extending the acquisition time. Good resolution is vital, as is sensitivity. The advent of higher powered instruments has helped in both respects and ^2H NMR spectroscopy is now one of the main techniques of biosynthetic study. As molecules increase in size, however, lines become relatively broader, and it has been reported that the technique was unsuitable on this account in a study of corrin biosynthesis.¹² It is advisable to check this point by running the natural abundance ^2H NMR spectrum of the metabolite, before embarking on extended incorporation studies with labeled compounds.

1 INTRODUCTION

The parameters measurable in NMR spectra—chemical shifts, coupling constants, relaxation times and the nuclear Overhauser effect (NOE)—reflect faithfully, though in ways that are not always easy to decipher, the electric and magnetic forces acting in the environment of the observed nucleus, and hence the structure and dynamics of this environment. In the words of John Wertz, author of the first review of chemical applications of NMR in 1955: ‘Atomic nuclei act as spies sending out radio signals reporting on the properties of their environment.’¹ If the nucleus is part of only a single atom or a simple small molecule, a simple and rigorous physical theory will account for the magnitude of each of the parameters measured. As the complexity of the system—in essence the number of neighbors in close proximity—increases, so does the number of contributions that are reflected in each parameter. The theory, though still applicable in principle, loses its rigor. It is not possible to measure each of the contributions individually, but only their sum. Nor is it possible to compute the interactions between all neighbors precisely, because of their large number. For systems as large and complex as biological macromolecules, the interpretation of NMR parameters in terms of their structure and dynamics rests on qualitative—at best, semiquantitative—arguments. The fact that it is nevertheless possible to extract an enormous amount of structural and dynamic information from the NMR spectra of macromolecules reflects the wealth of empirical findings obtained over the past 40 years. These have shown that certain structural and dynamic features of a macromolecule exert a very pronounced effect on the NMR parameters of nuclei embedded in it that can be interpreted, even if not measured exactly. To cite but a few examples, chemical shifts are known to change as a peptide segment forms a helix, coupling constants change if the rotation of a backbone or side chain is restricted, and relaxation parameters reflect distances to nearby nuclei. The theoretician, faced with the hopeless task of disentangling the sum of dozens of components whose individual magnitudes cannot be measured, has thus been helped by the experimentalist. As the number of empirical correlations multiplies, an increasingly precise interpretation of NMR parameters in terms of macromolecular structure and dynamics becomes possible.

The purpose of this article is to summarize the information content of NMR parameters as measured on macromolecules. The text of this section is a condensation and update of the more extensive treatment given in Chapters I, II and IV of Jardetzky and Roberts, ‘NMR in Molecular Biology’.² To be found elsewhere in this work are the elementary theory of the parameters and details of empirical correlations that have been established. Suffice it to say here that: the mechanism of the chemical shift arises from the polarization of the electron cloud around each nucleus by the external magnetic field of the spectrometer. This causes the electron cloud to generate an opposing magnetic field, thus ‘shielding’ the nucleus. The magnitude of the chemical shift depends on the density and symmetry of the electronic charge surrounding the nucleus. This in turn depends in the first instance on the distribution of chemical bonds in the molecule, and in the second on the polarization of the electron charges comprising the bonds by surrounding electric and magnetic fields originating both in the molecule and in the surrounding solvent. The physical principle of spin–spin coupling is fundamentally the same, except that the polarizing field in this case arises from a neighboring magnetic nucleus connected to the observed nucleus by the electron cloud of one or more chemical bonds. Since the external field depends on the experimenter, whereas the field of a neighboring nucleus does not, one will find that the chemical shift depends on the imposed external field, i.e. on the spectrometer frequency, but spin–spin coupling does not. On the other hand, spin–spin coupling will depend on the orientation of the polarizing nuclei with respect to the external field—splitting the observed line into two or more components that correspond to different orientations in the external field.

The most important physical mechanism of relaxation in macromolecules is direct through-space magnetic coupling between two nuclear magnets. In this case, better quantitative interpretation is possible than in the case of chemical shifts, coupling constants and of relaxation parameters dominated by chemical shift anisotropy or quadrupolar coupling. This is due to the fact that the theory of pure magnetic coupling between permanent nuclear magnets is simpler than it is for coupling that involves polarizable electronic structures.

2 NMR PARAMETERS

2.1 Chemical Shift

The range of chemical shifts observed in biological macromolecules is roughly the same as that observed for small molecules. The experimentally found ranges for nuclei of biological interest are shown in Figure 1. The chemical shift between two resonance lines is directly proportional to the observing spectrometer frequency. To correct for this known dependence, shifts, δ , are generally given in parts per million (ppm) relative to a spectral line chosen as a standard and calculated from the formula:

$$\delta = \frac{\nu - \nu_0}{\nu_0} \times 10^6 \quad (1)$$

2 BIOLOGICAL MACROMOLECULES: NMR PARAMETERS

Figure 1 Ranges of chemical shifts for ^1H , ^{13}C , ^{15}N , ^{17}O and ^{31}P . (From Jardetzky and Roberts²)

where ν and ν_0 are the frequencies of the shifted and the standard reference spectral lines, respectively; ν_0 is effectively the spectrometer frequency. Normalization to the observing frequency makes it possible to compare directly shifts observed at different frequencies and to evaluate the shift as a characteristic of the molecule, independent of the conditions of observation.

The foregoing definition of δ applies only to the averaged chemical shift observable in solution. Within the molecular framework, the chemical shift cannot be described by a single number, because the distribution of electrons around each nucleus is not spherically symmetric (except for isolated atoms), and the magnitude of the shift will depend on the orientation of the molecule with respect to the external magnetic field. This is clearly demonstrable by NMR experiments on molecules oriented in the solid state. In general, the chemical

shift must be represented by a second-order tensor (nine numbers), but it is usually sufficient to describe it as a first-order tensor:

$$|\delta| = \begin{vmatrix} \delta_{xx} & \delta_{xy} & \delta_{xz} \\ \delta_{yx} & \delta_{yy} & \delta_{yz} \\ \delta_{zx} & \delta_{zy} & \delta_{zz} \end{vmatrix} \quad (2)$$

where δ is the shielding constant. Only in the case of completely isotropic tumbling does one observe the single value averaged to spherical symmetry by isotropic molecular motion. When interpreting shifts on biological macromolecules it is therefore very important to ascertain the adequacy of averaging for each system under study. Some macromolecules—especially the rod-like nucleic acids—may

orient in the external magnetic field, in which case the component of the chemical shift tensor aligned with the observing radiofrequency field will largely be seen.

Examination of Figure 1 reveals the well-established general pattern of ^1H and ^{13}C chemical shifts. Taking amino acids as examples, methyl proton resonances appear at lowest frequency (0.8–1.6 ppm), followed by methylene protons (1.1–4.1 ppm), α -CH protons (3.0–4.5 ppm), and aromatic protons (6.9–8.8 ppm). A similar pattern can be seen for ^{13}C : methyl carbon atoms (10–30 ppm), methylene (30–60 ppm), and α -carbon atoms (50–70 ppm) resonating at progressively higher frequency, followed by aromatic carbon atoms (120–140 ppm), the guanidino carbon atom of arginine (150 ppm), and carboxyl carbon atoms (160–180 ppm). Within each of these broad categories, the effects of substituent electronegativity on the chemical shifts can be clearly discerned. For example, the hydroxyl substituent in serine shifts both the ^{13}C and ^1H resonances of the β -CH group to higher frequency. In threonine and alanine the methyl proton resonances are shifted to significantly higher frequency of those of valine, leucine, and isoleucine due to the electronegative substituents on C- β and C- α , respectively, while in lysine and arginine the methylene group attached to nitrogen in the side chain also has its ^1H and ^{13}C resonances shifted to higher frequency.

A useful distinction can be made between the *intrinsic* chemical shift, which depends only on the properties of the covalent molecular structure surrounding the nucleus, and the *extrinsic* or environmental chemical shift, comprising contributions arising from surroundings that are not part of the immediate covalent structure. The distinction is clear-cut for small molecules, where the electronic structure of the molecule determines the former and properties of the solvent determine the latter. In macromolecules the distinction is slightly blurred, since environments within a folded structure are generated by neighbors whose covalent connection to the observed nucleus is through a long chain of bonds. The distinction nevertheless remains useful, especially for purposes of calculation, since it distinguishes between effects that are transmitted through the intervening chemical bonds from those transmitted through space. The structural chemical shifts observed in folded proteins are for the most part extrinsic. Three kinds of structural chemical shift have been empirically shown to be of diagnostic value in structural studies of biological macromolecules: (1) the stacking shifts, (2) the secondary structure shifts, and (3) tertiary folding shifts. Stacking shifts are observed when groups are placed in the vicinity of aromatic rings—typically two nucleic acid bases or two phenylalanine rings stacked in parallel, or a methyl group placed in the structure above a tryptophan ring. The highly anisotropic aromatic or heterocyclic rings generate strong, anisotropic magnetic fields when placed into an external field. Generally, nuclei placed in the plane of the ring experience a high frequency shift, whereas those placed above or below the plane of the ring experience a low frequency shift. These shifts can be quite large (up to 3–4 ppm) and the stacking shift is the main reflection of helical structure in nucleic acids. Typical secondary structure shifts in proteins have first been observed for the α -CH groups of amino acids and are smaller (on average, +0.4 ppm to low frequency for α -helices and –0.3 ppm to high frequency for β -strands).³ Tertiary structure shifts generally (including stacking shifts for proteins) reflect

the environment created by the folding of a protein chain and vary in the range 0.2–4 ppm. Their magnitude and direction depend on a variety of factors—all of which reflect proximity in space of charges, polar groups, hydrophobic groups, double bonds, etc.

The systematic analysis of chemical shifts in proteins and nucleic acids, especially of the structural shifts, is a difficult and incompletely solved theoretical problem. At the same time, the existence of structural shifts and a qualitative understanding of their nature is the basis for all structural and dynamic studies of proteins and nucleic acids by NMR. If structural shifts did not exist, chemically equivalent amino acid residues in a protein could not be distinguished, assignment of separate spectral lines to residues in different parts of the structure would not be possible, and neither would be the determination of three-dimensional structures and detailed studies of their behavior.

The fact that the spectrum of a folded protein depends on the nature of the folding was first conclusively demonstrated in the years 1964–1968 by comparisons of the spectra of native and denatured proteins, as well as of helical and random coil amino acid homopolymers.^{4–6} The equivalent modern experiment illustrating this fundamental finding is shown in Figure 2. The magnitudes of the different kinds of structural shifts empirically established in our original experiments at that time⁶ have recently been confirmed by analysis of much more extensive experimental material that has since become available.

Both theoretical calculations⁷ and statistical analysis^{8–10} have shown that the C- α proton chemical shift of an amino acid residue in peptides and proteins is shifted to low frequency (lower chemical shift values) in α -helices and to high frequency (higher chemical shift values) in β -strands in comparison to those in the random-coil structure. The degree of overlap of values is remarkably small, making the examination of the C- α proton chemical shifts an easy method for a preliminary qualitative check for the presence of secondary structure elements. Also, similarities among

Figure 2 500 MHz ^1H NMR spectra of hen lysozyme in D_2O . (a) Thermally denatured (85 °C) protein; (b) native (40 °C) protein

homologous proteins have been used to help the assignment of the spectra or to interpret the shift.

Similar trends have been observed for amide proton chemical shifts,^{9,10} and an opposite trend for side chain proton chemical shift values, i.e. α -helices induce a shift to higher frequency while β -strand conformations induce a low-frequency shift. However, the degree of overlap of values displayed by these two groups of protons limits the degree of conformational information extractable from chemical shifts. On the other hand, the shifts of amide protons are very sensitive to hydrogen bonding^{10,11} and this observation could constitute a practical application. Since the strength of hydrogen bonds is related to distance, amide chemical shift data could be used to determine intramolecular distances, providing oxygen to proton distances as additional restraints. This kind of information could greatly improve the quality and accuracy of protein structures determined by NMR spectroscopy. However, much work on this regard is clearly needed before this method can reach its full potential.

Other relationships between proton chemical shifts and protein conformation have been observed, such as a correlation between proton amide chemical shifts and helix dipole effects, as well as a relationship between C- α proton chemical shifts and main-chain flexibility or backbone dihedral angles.¹⁰ These observations are worthy of further investigation.

The improvement of isotopic substitution strategies and the development of new methodologies of heteronuclear two- and three-dimensional NMR provided a larger number of peptides and proteins with nearly complete ^{13}C and ^{15}N sequential assignments, making possible the analysis of the dependence of the chemical shifts of these nuclei on secondary structure. The examination of the ^{13}C - α , ^{13}C - β and amide ^{15}N chemical shifts also revealed a dependence on the secondary structure;^{7,12} however, the trends are less clear than in the case of C- α and amide protons, due to the small data base available up to now.

Although the chemical shift value carries information about folded structures, it rarely by itself provides sufficient quantitative information to draw unequivocal structural conclusions. The reason for this is that the individual determinants of chemical shifts are in general known only qualitatively. The principal determinants are summarized in Table 1. The early work developed by Lamb, Ramsey, Pople, and Buckingham for quantitative calculations, discussed elsewhere,² has for many years provided rough guidelines in the face of a lack of suitable physical data with which accurately to define the parameters needed in the calculations. The observed chemical shift for any nucleus in a biological macromolecule must be analyzed as a structure-dependent sum of several individual contributions—including the empirically identified structural shifts. The individual components of the sum can be identified, as in the equation:

$$\delta_{\text{obs}} = \delta_{\text{electrostatic}} + \delta_{\text{dipolar}} + \delta_{\text{induced dipolar}} + \delta_{\text{solvent}} + \delta_{\text{double bonds}} + \delta_{\text{ring current}} \quad (3)$$

These components are not truly independent and additive, however, but the magnitude of each depends on that of several others because each term contains the polarization of each contributing atom, and that, in turn, has a strong dependence on the polarization of every atom in the vicinity.

Until very recently it has not been possible to calculate chemical shifts in proteins. Although theoretical models have

Table 1 Principal Determinants of Chemical Shifts^a

Electric effects (exerted by electric fields which polarize electrons surrounding the observed nucleus and change their induced magnetization):

1. Nearby charges (e.g. H^+ , Na^+ , NH_3^+ , Mg^{2+} , Cl^- , PO_4^{2-})
2. Nearby permanent dipoles (HOH , $-\text{NH}_2$, $\text{C}=\text{O}$, polar groups generally)
3. Nearby induced dipoles, especially if observed nucleus is part of a polar group (all structures are polarizable)

Magnetic effects (magnetic fields of neighboring structures):

1. Double and triple bonds, (e.g. $\text{CH}=\text{CH}$, $\text{C}(\text{O})=\text{O}$, $\text{HNC}=\text{O}$)
2. Ring currents of aromatic and heterocyclic rings
3. Species containing unpaired electrons (ions and free radicals)

^aThe two types of effect are separable only by order of magnitude. Magnetic fields of neighboring structures are also subject to polarization effects by nearby electric fields. Electron currents surrounding the observed nucleus are subject to change by neighboring magnetic fields.

been available for many years, the lack of assigned signals in proteins with well-characterized three-dimensional structures, precluded the test of the models and the derivation of parameters suitable for proteins. However, two-dimensional and three-dimensional NMR techniques have yielded a number of protein assignments, providing the experimental data to test the models. It has been shown that chemical shifts can be calculated using the existing models, to a reasonable degree of accuracy.^{13,14}

The best understood conformation-dependent contribution to chemical shifts is the ring-current contributions associated with conjugated groups. For protein side-chain protons, the ring current theoretical forms reasonably explain large structural shifts, with linear correlations between calculated and observed shifts in the range of 0.7–0.8 and root-mean-square (rms) errors of 0.2–0.4 ppm.^{15–17} The correlation is poorer for C- α and amide protons of the backbone,^{15–17} suggesting that additional mechanisms contribute for structural chemical shifts in these cases. Additional contributions that might operate as well are magnetic anisotropy of the peptide group and electrostatic and hydrogen-bonding effects. In fact, it has been shown that the introduction of magnetic anisotropy and electric field contributions, in addition to ring-current contributions, significantly improve the correlation between observed and calculated chemical shifts for C- α protons to the range of 0.8–0.9, with rms errors of 0.18–0.3.^{13,14} The correlation between chemical shifts and secondary structures tends to improve as the factors determining the extent of the shift are better understood. An additional factor that has to be taken into account is that proteins are mobile in solution, therefore, the observed shift value might result in a conformational average.

In recent years, with the increasing application of high-speed computation to solve many-body problems numerically, progress in the precision of quantum calculations and a better definition of interatomic potentials through the experience with molecular dynamics, more quantitative approaches to the calculation of chemical shifts have aroused renewed interest. One promising approach is for ab initio calculation of chemical shifts in proteins, discussed elsewhere in this volume (see *Chemical Shifts in Biochemical Systems*). It should be noted, however, that a quantitative calculation

of all chemical shifts, including especially the structural shifts, requires prior knowledge of the structure. The distance dependence of chemical shift contributions from surrounding fields of the type listed in Table 1 is inextricably linked with the magnitude of the induced electronic dipoles. As already noted, these in turn reflect the highly distance-dependent mutual polarization of all surrounding atoms, introducing the need to consider higher order interaction terms, and making a simple determination of any single distance for all practical purposes impossible. Qualitatively, proximity can often be inferred from dramatic changes in chemical shifts, and this has been shown to be useful in the study of molecular complexes of macromolecules with small ligands. A very rough topology of the complex can, in fact, be defined on that basis.¹⁸ Beyond that, geometric information not available from chemical shifts is needed to make a quantitative calculation. It may be expected, nevertheless, that as the accuracy of chemical shift calculations for a known protein or nucleic acid geometry improves, the calculated chemical shifts will be able to serve as a double-check on the correctness of the structure and a guideline for its refinement.

2.2 Coupling Constants

Coupling constants arise from the interactions between neighboring atomic nuclei mediated by the intervening chemical bond (or bonds). The electron cloud of the intervening bond is polarized by the mutual orientation of two (or more) neighboring nuclei. Since nuclei assume only a discrete number of orientations in an external magnetic field, the resonance position of each nucleus will undergo a discrete set of changes resulting from this additional polarization. In the simplest case of two nuclei of spin 1/2, each of the two spectral lines will be split into a doublet, corresponding to an orientation of the neighbor against the external field. Groups of two or more identical nuclei will produce more complex patterns, as shown in Figure 3. The frequency separation between two peaks of a multiplet is a measure of the coupling constant, J .

Coupling constants in the spectra of biological macromolecules are of great practical importance for several reasons. First, the characteristic coupling patterns within the side chains of amino acid residues serve to identify the spectra of specific amino acids and establish a 'first stage' assignment of the spectrum of amino acid type. Second, scalar coupling, especially that involving the (larger) heteronuclear coupling constants, can be useful for tracing covalent connectivities along the polypeptide chain, thus aiding in the sequential (residue specific, 'second stage') assignment of the spectrum (see *Biological Macromolecules*). Third, coupling constants across three

covalent bonds can provide information on the magnitude of the intervening dihedral angle, thus aiding in the definition of both the peptide chain and side-chain conformations.

Typical ranges of coupling constants between neighboring nuclei observable in biological structures are given in Table 2. The use of coupling patterns in conjunction with the known chemical shift pattern, to identify amino acid side chains in a two-dimensional COSY spectrum is shown in Figure 4.¹⁹ The ease of distinguishing between most, though not all of the amino acids in a complex spectrum is readily apparent. It is worth noting that the patterns and the values of the coupling constants observed reflect free rotation around most of the side chain bonds. This free rotation is observable in amino acids, peptides and proteins. One important exception is the rotation about the $\alpha\text{-CH}-\beta\text{-CH}_2$ bond in larger peptides and proteins, where the rotation is often hindered, so that separate coupling constants $\alpha-\beta$ and $\alpha-\beta'$ can be resolved. The exception is important, inasmuch as it makes it possible to derive geometric information from the two coupling constants, as discussed below. Geometric information cannot be obtained from coupling constants averaged by rotation around a single bond.

Figure 4 Diagram of the COSY spin–spin connectivities pattern for the 20 common amino acids. (From Lichtarge¹⁹)

The use of homo- and heteronuclear coupling constants for the sequential assignment of protein spectra is discussed elsewhere in this Encyclopedia. Of considerable general importance is the fact that the possibility of using coupling constants for this, as for all other purposes, is limited by the ability to resolve them. In contrast to chemical shifts, coupling results in relatively small line separations, which are independent of the external field and hence cannot be improved by the use of higher frequency spectrometers. The resolution of coupling constants is therefore primarily sensitive to linewidths, and these in turn to the molecular weight of the macromolecule. The use of proton coupling constants for sequential assignment is generally limited to proteins <10 kDa, since most of the relevant NH– α -CH constants are of the order of 3–5 Hz. The corresponding use of heteronuclear coupling constants on normal (fully protonated) proteins appears limited to structures <30 kDa, since the limiting constant across the peptide bond (between the CO(*i*) and NH(*i* – 1)) is of the order of 8–15 Hz. It becomes unobservable at higher molecular weights. The possibility of extending the use of coupling constants to structural studies on larger macromolecules by using extensively deuterated analogs to reduce line broadening has been suggested and demonstrated in the case of the *trp*-repressor–DNA complex (37 kDa), the largest structure thus

far solved by NMR. The ultimate molecular weight limit for the use of coupling constants still remains to be established.

Coupling constants are an important and frequently used, but not foolproof, source of geometric information on biological macromolecules. As in the case of chemical shifts, the theoretical calculation of coupling constants has met with only limited success, since it depends on detailed knowledge of electron distributions, which is missing in most cases. The relative contributions of σ - and π -electrons to the magnitude of *J* in different systems, evaluated by the equations developed by Ramsey²⁰ and McConnell,²¹ are to be understood as rough, rather than accurate, estimates. Nevertheless, some useful relationships between coupling constants and structural parameters have a semitheoretical basis.

Of greatest interest in biochemistry is the relationship between the magnitude of the coupling constants across three bonds (vicinal coupling constants) and the dihedral angle θ about the central bonds (see Figure 5). It was originally derived for coupling in the $^1\text{H}-\text{C}-\text{C}-^1\text{H}$ fragment by the theoretical calculations of Karplus²² and can be approximated in the form:

$$J = A + B \cos \theta + C \cos^2 \theta \quad (4)$$

Figure 5 Dihedral angle, θ formed by the H-C-C and C-C-H planes. (From Jardetzky and Roberts²)

where A , B , and C are coefficients that depend upon the electronegativity of the surrounding atoms. The values of A and C , originally calculated from theory (B was taken as zero), have generally been superseded by semiempirical values calibrated on specific groups of compounds. In some forms of the Karplus relation an electronegativity correction is explicitly introduced, while in others it is reflected in the magnitude of coefficients A , B , and C .

The Karplus relationship [equation (4)] suggests that it might be possible to determine conformations about any single bond that lies between two bonds connecting to atoms observable by NMR. 'Karplus relations' have been developed for $^1\text{HNC}^1\text{H}$, $^{31}\text{POC}^1\text{H}$, and many other molecular fragments. The form of the dependence of J on θ is shown in Figure 6.^{23–26} Two points are generally relevant to all relations of this type and should always be borne in mind:

1. The relationship between coupling constant and dihedral angle [equation (4)] is valid for a rigid molecular fragment. In flexible molecules the averaging of J and θ follows different rules since the dependence of J on θ is not linear. Therefore, the proper average θ cannot be calculated from the observed average J . If this is not taken into account, wrong conclusions about the structure will be drawn.²⁷
2. The relationship is a truncated cosine expansion and as such an approximation; its inherent precision is not very great, particularly since the coefficients are semiempirical. It characterizes the general trend of the angular dependence of the coupling constant, but the limits of the precision with which an angle can be estimated from equation (4) are unknown, even for a rigid molecular fragment.

Figure 6 The Karplus curve: the coupling constant, J , as a function of the dihedral angle, θ , for amide compounds.^{23–26} (From Lichtarge¹⁹)

Karplus-type curves have been calibrated for heteronuclear constants across the peptide bond, especially by Bystrov.²⁵ Calibrations of this type are now frequently being used for the purpose of defining protein structures. However, the error bars on all calibrations of the Karplus relationship are rather large, so that very precise statements about the values of the dihedral angles derived from them are likely to involve an overinterpretation of the data. In contrast, the broad general features of a molecular conformation derived from Karplus curves are likely to be valid, if one is dealing with a segment with restricted rotation or, in the case of flexible molecules, if averaging has been properly taken into account.

2.3 Relaxation Parameters

The relaxation parameters—respectively, spin–lattice relaxation time (T_1), spin–spin relaxation time (T_2), spin–lattice relaxation time in a rotating coordinate system ($T_{1\rho}$), and nuclear Overhauser effect (NOE)—were first used for structural studies on biological macromolecules as early as 1961²⁸ and have retained a prominent role in modern studies of macromolecular structure and dynamics. Their importance derives from the fact that they reflect a relatively simple relationship between the experimentally observed quantities and internuclear distances. Unlike the chemical shifts and coupling constants, which depend on polarizable electron clouds and their highly variable induced magnetic fields, relaxation parameters depend on the interaction between permanent dipoles.

Information on protein dynamics can be extracted from values of the relaxation times T_1 and T_2 . Regions affected by fast or slow motions, conformational flexibility, disordered regions, helix–coil transitions, 'breathing' motions and dynamic states of partially folded structures can be identified by anomalous values of the relaxation times.

The most detailed information comes from the NOE, the magnitudes of which can be used to determine constraints in proton–proton distances, and, in turn, to generate three-dimensional structures. The basic two-dimensional NOE experiment is obtained from a three pulse sequence:²⁹ (delay time $-90^\circ - t_1 - 90^\circ - \tau_m - 90^\circ - t_2$)_n, where τ_m is the mixing time. Double Fourier transformation with respect to times t_1 and t_2 result in the two-dimensional NOE spectrum containing the cross peaks, whose intensities are proportional to the inverse of the sixth power of the distance, r , between the protons, and to the correlation time (τ_c):

$$\text{NOE} \propto \left\langle \frac{1}{r^6} \right\rangle f(\tau_c) \quad (5)$$

The main complications in the relationship between the measured relaxation parameter and the molecular structural parameter—the internuclear distance—is the simultaneous dependence of relaxation on the rates of molecular motion, which are subjected to some variation. Other factors complicating the relationship between relaxation and molecular parameters may be the operation of relaxation mechanisms other than dipole–dipole interaction, such as chemical shift anisotropy, scalar or quadrupolar coupling and exchange. If there is no reason to believe that such mechanisms play a non-negligible role, their contribution must be quantitatively evaluated.

Table 3 Relaxation MechanismsObserved total relaxation rate $(1/T_1)_i$:

$$(1/T_1)_i = (1/T_1)_{pi} + (1/T_1)_{Di} + (1/T_1)_{\sigma i} + (1/T_1)_{pi}$$

$$(1/T_1)_p = \hbar^2 \gamma_p^2 \left(\frac{3}{2} \gamma_p^2 \sum_j r_{ij}^{-6} \tau_{pij} + \gamma_f^2 \sum_f *r_{if}^{-6} \tau_{pif} \right)$$

$$(1/T_1)_D = \hbar^2 \gamma_p^2 \left(\frac{3}{2} \gamma_p^2 \sum_k r_{ik}^{-6} \tau_{Dijk} + \gamma_e^2 \sum_e *r_{ie}^{-6} \tau_{Die} \right)$$

$$(1/T_1)_\sigma = \frac{2}{15} \gamma_p^2 H_z^2 (\Delta\sigma)^2 \tau_\rho$$

$$(1/T_1)_p = \left(\frac{3\gamma_p^2 \mu_{\text{eff}}^2}{r_{is}^3} \right) N_s \tau_{Dis}$$

For nuclei with a quadrupole moment, an additional term applies:

$$(1/T_1)_Q = \frac{3}{8} \hbar^2 (eQ)^2 (eq)^2 \tau_c$$

 $(1/T_1)_{pi}$ is the relaxation rate resulting from interaction with nuclei in the same molecule (intramolecular or rotational relaxation). $(1/T_1)_{Di}$ is the rate resulting from interaction with nuclei in other molecules (intermolecular or translational relaxation). $(1/T_1)_{\sigma i}$ (shielding anisotropy term) is the rate resulting from interaction with magnetic fields generated by shielding anisotropy. $(1/T_1)_{pi}$ (paramagnetic term) is the rate resulting from interactions with the magnetic moments of unpaired electrons. γ_p , γ_f and γ_e , respectively, the gyromagnetic ratios of nuclei of the same and of a different chemical species as nucleus i ; r_{ij} , r_{if} , r_{ik} and r_{ie} , the internuclear distances; r_{is} , the distance between nucleus i and an impartial electron. τ_ρ , the correlation time for rotational diffusion; τ_D , the correlation time for translational diffusion for pairs of particles ij , ik , etc.

Correlation times for intramolecular and intermolecular movements of a rigid molecule are expressed in terms of the diffusion coefficient of the molecule containing the relaxing nucleus:

$$(\tau_c)_{\text{intra}} = \frac{2a^2}{9D} \quad \text{and} \quad (\tau_c)_{\text{inter}} = \frac{r^2}{12D}$$

where a is the radius of the molecule, r is the average intermolecular distance, and D is the diffusion coefficient. D is given by the Stokes–Einstein relationship:

$$D = \frac{kT}{6\pi\eta a}$$

where k is the Boltzmann constant, T is the absolute temperature, η is the viscosity, and a is the molecular radius.

The basic theory of relaxation parameters is discussed elsewhere in this work. The different relaxation mechanisms and their dependence on molecular parameters are summarized in Table 3.

Unfortunately, a set of rigorous criteria for distinguishing between the different relaxation mechanisms does not exist, except for the ideal case of a rigid structure with a single resonance line and a single dominant relaxation mechanism. Field or frequency dependence of the relaxation rates can provide useful guidelines, since for a rigid structure relaxation rates will decrease with increasing field if the mechanism is dipolar or quadrupolar, and increase proportionately to the square of the field if the mechanism is chemical shift anisotropy. Either an increase or a decrease with increasing field may be observed for a scalar mechanism. However, for flexible systems, and wherever several mechanisms operate simultaneously, these simple relationships may be obscured. Heterogeneity of chemical shifts and relaxation rates, unobservable at lower field, may also make quantitative comparisons difficult. Information or intuition to the NMR measurement will often be required to make a decision.

Even in the case of pure dipolar relaxation, intuition and judgment are required to decide which form of the relaxation equations for the calculation of the experimental relaxation parameters actually applies to a given situation. For the simple case of two isolated spins on a rigid body, the dipolar component of the relaxation equations can be written in the form:

$$\begin{aligned} \frac{1}{T_1} &= \frac{9}{8} \frac{\gamma^4 \hbar^2}{r^6} \{J(\omega) + J(2\omega)\} \\ \frac{1}{T_2} &= \frac{9}{32} \frac{\gamma^4 \hbar^2}{r^6} \{J(0) + 10J(\omega) + J(2\omega)\} \\ \text{NOE} &= 1 + \frac{\{6J(\omega_H + \omega_C) - J(\omega_H - \omega_C)\}}{\{J(\omega_H - \omega_C) + 3J(\omega_C) + 6J(\omega_H + \omega_C)\}} \end{aligned} \quad (6a)$$

where the spectral density function, $J(\omega)$, is given by a single Lorentzian term:

$$J(\omega) = \frac{\lambda}{\omega_0^2 + \lambda^2} \quad (6b)$$

Strictly speaking, this simple formulation never applies to biological macromolecules, and when it applies, represents a drastic oversimplification. The oversimplification can be useful to get a rough impression of the structural parameters reflected in the relaxation parameters, but it is a mistake to treat it as a source of accurate and precise information.

In macromolecules, two complicating factors have to be taken into account. The first one is that any observed nucleus interacts not with one, but generally with several of its neighbors, and each of these, in turn with each of the others. Multiple interactions can be taken into account by generalized Bloch equations:

$$\frac{dM_i}{dt} = -\rho_i [M_i - M_i(0)] - \sum_{ij} \sigma_{ij} [M_j - M_j(0)]; \quad i \neq j \quad (7)$$

which can also include different spectral density functions for different pairs of nuclei. The equation describes multiple pathways—or diffusion—of magnetization transfer within a system of spins, replacing magnetization exchange between two spins. This has become known as ‘spin diffusion’, borrowing the term with a slightly altered meaning from solid state physics. The importance of spin diffusion stems from the

fact that the intensity of magnetization observed at any given time—and hence the magnitude of the calculated relaxation parameters—may be more or less than the magnitude predicted from the simple relationship in equation (6). A wrong estimate of the distance would be obtained without a correction for spin diffusion. In structure determination, the generalized Bloch equations are now commonly used for the back-calculation of spectra to verify and refine an approximate starting structure derived from equation (6). Structural information is thus derived not from a single relaxation parameter for each nucleus, but from the sum total of the interactions determining the pattern of relaxation. The multispin relaxation effects can be fully accounted for if one manages to measure the complete density matrix $\mathbf{V}_{t_m}$. The relaxation matrix can then be obtained from:

$$\mathbf{R} = -\ln\left(\frac{\mathbf{V}_{t_m}}{\mathbf{V}_0}\right)\left(\frac{1}{t_m}\right) \quad (8)$$

where $\mathbf{V}_0$ represents the intensities of the diagonal peaks at $t_m = 0$ (corresponding to the one-dimensional spectrum) and $\mathbf{R}$ is the relaxation matrix. The proton distances can be derived from the corresponding off-diagonal elements of the relaxation matrix $\mathbf{R}$. The measurement of all the intensities, including diagonal peaks, is an unattainable goal in real cases. Consequently, several iterative approaches have been developed to cope with incomplete intensity information. All the approaches are designed to minimize the deviation between measured and calculated intensities. They can be divided into two classes. The first class utilizes the self-consistency of the relaxation matrix, modifying the matrix until there is agreement between calculated and measured intensities. The most popular program of this class is called MARDIGRAS.³⁰ In the second class, a comparison between the theoretical and experimental intensities is used to define how close the structure is to the experimental data, while refining the structure, with the help of distance geometry of molecular dynamic methods. The algorithm IRMA was developed under this approach.³¹

The second complicating factor that has to be taken into account is that when multiple internal motions occur, as they do in biological macromolecules, the explicit form of the density function, $J(\omega)$, can be quite complicated, and different for different pairs of nuclei. The calculation of a specific density function for each pair of nuclei requires a specific motional model. As discussed elsewhere in this Encyclopedia (see *Biological Macromolecules*), the formulation of accurate models for internal motions occurring in biological macromolecules is still in its infancy. Until the problems of such motions are better understood, we are limited to crude, and rarely accurate, approximations.

3 AVERAGING OF NMR PARAMETERS—FAST EXCHANGE

Many molecular processes have rates much more rapid than the rates reflected in NMR spectra (10 – 10^4 s^{-1} , not counting relaxation phenomena). Rotational diffusion occurs at rates of 10^6 – 10^{12} s^{-1} . Rotations about single bonds may have frequencies in the microwave and infrared region (rates of 10^{10} – 10^{13} s^{-1}). Diffusional collisions have typical frequencies

of 10^7 – 10^9 s^{-1} and even the ‘slow’ conformational changes in macromolecules detected by various spectroscopic methods can occur at rates of 10^4 – 10^6 s^{-1} . It is therefore to be expected that observed NMR parameters will often be averaged by molecular motions. While the interpretation of NMR data for the slow and intermediate exchange cases is relatively straightforward, for the rapid exchange case it is not. The observation of an average is not immediately informative. To extract the desired information from the measurement of average properties—or at least to understand the limits of the information that can be derived from such measurements—the nature of the averaging must be understood. This problem has been largely neglected in the NMR literature and as a consequence many untenable conclusions, especially concerning the conformations of flexible molecules, have been reported.

The core of the problem is that no direct indication can be obtained from an averaged spectrum, either concerning the number of molecular species or states contributing to the average, or concerning the characteristics of their individual spectra. In some cases it may be possible to set a lower limit to the number of species involved. In most cases, however, the spectrum must be interpreted in terms of a hypothetical model of the equilibria involved, and if this model does not correspond to the real situation, the structural parameters derived from the analysis will not have the anticipated meaning.

The problems of averaging can be best understood in the context of conformational analysis, although exactly the same principles apply to the study of the fast exchange processes, such as occur in molecular interactions. Consider the two potential energy diagrams shown in Figure 7. Figure 7(a) corresponds to a single conformation, permitting oscillation about a single distance or angle, or more generally, to a rigid body held together by vibrating bonds. We will call averaging about a single minimum *averaging of the first kind*. Isotropic averaging, as in rotational diffusion, may be regarded as a limiting case of this type, the potential energy curve being flat for all possible orientations. Figure 7(b) corresponds to the averaging of well-defined conformations, each corresponding to a well-defined energy minimum; for example, averaging of the rotamers about a single bond or averaging of the T and R states in the Monod–Wyman–Changeux model of conformational transitions in proteins. We will refer to this as *averaging of the second kind*.

Now suppose that the NMR data obtained for a given system are interpreted in terms of a model involving one single, fixed conformation. It can easily be seen that the geometric parameters derived from the data, and the structures deduced from them, have a physical meaning only if the real situation corresponds to Figure 7(a), the single minimum. This is the only case in which a single preponderant value of r or θ exists, and the measured average NMR parameter will reflect it. Even in this case some caution is necessary, since this is strictly true only if the averaging is symmetric. If the energy well (Figure 7) is asymmetric, as it often is for interatomic distances, $\langle r \rangle_{av}$ or $\langle \theta \rangle_{av}$ may differ somewhat from the r and θ corresponding to the energy minimum. However, if the minimum is relatively sharp, the error may be small and might be neglected. In that case the structure behaves for purposes of computation as if it were rigid, except for the vibrations.

Figure 7 Potential energy diagrams illustrating (a) motional averaging about a single energy minimum, (b) motional averaging of different conformers. Each minimum corresponds to an actual conformer. Distance $\langle r \rangle_{av}$ or angle $\langle \theta \rangle_{av}$ corresponds to a value calculated from an averaged NMR parameter. (From Jardetzky and Roberts²)

All relationships between NMR and structural parameters will hold as a first approximation.

However, none of these relationships will hold if the real situation corresponds to Figure 7(b), i.e. if the averaging is of the second kind. It is often stated in the literature that analyzing the NMR data in terms of a 'single conformation' model, the conformation one obtains is the 'average' conformation. In fact, this is not the case, as shown by the following argument.²⁷ The physical averaging of distances and angles by exchange between, say, two states A and B will be linear,

$$\bar{r} = \alpha r_A + (1 - \alpha) r_B \quad (9)$$

where α denotes the fractional population of A. Similarly, the NMR parameters characteristic of the two states will average linearly, e.g.

$$\langle 1/T_1 \rangle_{av} = \alpha/T_{1A} + (1 - \alpha)/T_{1B} \quad (10)$$

However, since the NMR parameters have a nonlinear dependence on distances and angles, their average will reflect a nonlinear average of the latter. For example, $\langle 1/T_1 \rangle_{av}$ will yield $\langle r^6 \rangle_{av}$. It can easily be shown that this is not the same as the $\bar{r}$ of equation (9). Thus from equation (10)

:

$$\frac{J^*(\omega)}{\langle r \rangle_{av}^6} = \frac{\alpha J_A(\omega)}{r_A^6} + \frac{(1 - \alpha) J_B(\omega)}{r_B^6} \quad (11)$$

where $J^*(\omega)$ is the spectral density function assumed in the calculation, and $J_A(\omega)$ and $J_B(\omega)$ the true (unknown) spectral density functions for species A and B. Even assuming $J^*(\omega) = J_A(\omega) = J_B(\omega)$:

$$\langle r \rangle_{av} = \frac{r_A r_B}{[\alpha r_B^6 + (1 - \alpha) r_A^6]^{1/6}} \quad (12)$$

and clearly $\langle r \rangle_{av} \neq \bar{r}$. Similarly, it can readily be shown that coupling constants (from the Karplus equation) and chemical shifts yield conformational parameters that are not simply related to the conformations A and B or to their linear average. *The conformation calculated from the averaged NMR parameters will therefore not correspond to the average of the conformations assumed by the molecule.*

There is a further fundamental problem in the interpretation of $\langle r \rangle_{av}$, $\bar{r}$, or other 'average' conformational parameters. A basic assumption implicit in the equations for rapid averaging of the second kind, i.e. between several energy minima, is that the time spent in transit between states is negligible in comparison with the lifetime of each state. The lifetimes of individual states also define a timescale. The 'states' defined by $\langle r \rangle_{av}$, $\langle \theta \rangle_{av}$, $\bar{r}$ and $\bar{\theta}$ have an infinitesimal lifetime in this or any longer timescale. Thus, in situations where averaging of the second kind occurs, the 'average structures' calculated by applying any of the equations discussed earlier to the analysis of any measured averaged NMR parameter are fictitious; on the timescale of the real states assumed by the molecular structure, they do not exist. For a more complete discussion of the relationships between 'apparent' and 'true' geometric parameters in cases involving motional averaging, the reader is referred to Chap. IV of 'NMR in Molecular Biology' by Jardetzky and Roberts.²

The general relationships defining the 'average' structural parameters $\langle r \rangle_{av}$ and $\langle \theta \rangle_{av}$ derived from averaged NMR parameters, J and $1/T_{1,2}$, in terms of the individual values of r and θ for exchange between N energy minima are given in Table 4.

A meaningful analysis of NMR data in terms of structural parameters in the case of rapid averaging is therefore possible only if the correct model is used in the analysis of the data. NMR data generally do not provide criteria for the choice of a model, with few exceptions. Although some models can be disproved by NMR data alone, it can never be proved that the model being used does correspond to the real situation.

The interpretation of individual NMR parameters in terms of the structure, dynamics and function of biological macromolecules is thus seen to be less than straightforward. If it is nevertheless possible to draw very significant conclusions about macromolecular structure and dynamics, it is because these conclusions rest on the interpretation of the pattern of parameters observed for a macromolecule in its entirety rather than on the interpretation of any single parameter. The uncertainty inherent in the interpretation of a single parameter can be minimized by checks of consistency with the interpretation of other parameters. Averaging is a perennial problem that needs more attention than it has received, with the result that some of the published macromolecular structures remain open to doubt. In very few cases has a detailed analysis of the effects of averaging by molecular motions on different timescales been carried out, the most thorough being the case of the *trp*-repressor from *Escherichia coli*, in which

Table 4 Relationships of 'Average' Structural Parameters Derived from Averaged NMR Parameters to the Real Parameters for N Energy Minima

1. The distance $\langle r \rangle_{\text{av}}$ derived from averaged relaxation parameters

$$\langle r \rangle_{\text{av}} \equiv \langle r^{-6} \rangle^{1/6} = \frac{\prod_i^N r_i}{\left(\sum_i^N \prod_{j \neq i}^{N-1} \alpha_j r_j^6 \right)^{1/6}}$$

2. The dihedral angle $\langle \theta \rangle_{\text{av}}$ derived from averaged coupling constants

$$\langle \theta \rangle_{\text{av}} = \arccos \left\{ \frac{-B \pm \left[B^2 - 4C \sum_i^N \alpha_i (A + B \cos \theta_i + C \cos^2 \theta_i) \right]^{1/2}}{2C} \right\}$$

$$\langle \theta \rangle_{\text{av}} \neq \bar{\theta} = \sum_i^N \alpha_i \bar{\theta}_i$$

the DNA binding, helix–turn–helix domain shows an instability on a millisecond timescale.³² In general, it is to be expected that such an analysis will be necessary for most larger proteins and protein–nucleic acid structures. Macromolecules can only be completely understood in terms of a specific structural–dynamic model that correctly and completely accounts for the total of NMR parameters that can be measured in its spectra.

1 INTRODUCTION

The purpose of this article is to outline briefly recent progress in understanding chemical shifts in biochemical systems—proteins, nucleic acids, carbohydrates, and lipids. The chemical shift is probably the most sensitive spectroscopic probe of local structure and environment, but until quite recently it has been quite refractory to detailed analysis, at least in macromolecules. In small molecules, this sensitivity manifests itself in isotope shifts, temperature dependence, gas-to-liquid shifts, and solvent shifts. In macromolecules, sensitivity is manifested as chemical shift nonequivalencies. The NMR chemical shift in biological systems contains a wealth of encoded structural information, and in order to decode this information it is first necessary to be able to predict chemical shifts from known structures.

From a theoretical standpoint, insights gained in studying chemical shifts in biological systems should also greatly help in testing, modifying, and improving present theories of the chemical shift. For example, proteins provide a unique test case for investigating the dependencies of the chemical shift on factors such as torsion angles, hydrogen bonding, and electrostatics. In sharp contrast, gas phase studies of small molecules would not be capable of yielding the torsional dependencies of the chemical shift. This is because variable-temperature measurements, in which the torsional effects would be visible, also include significant contributions from centrifugal distortion, and, in addition, a change in one torsion angle may significantly change the overall shape of a small molecule, and consequently the way it interacts with its environment. Proteins, on the other hand, do not require variable-temperature studies, since sites which differ only in torsion angles are already present. Hence, the ability to interpret and reproduce chemical shift nonequivalencies in biological systems should not only be useful for structure elucidation, but is also of fundamental importance for the evaluation, development, and design of methods for chemical shift computation in general.

Chemical shift nonequivalencies due to folding have been known in proteins for more than two decades. McDonald and Phillips¹ first observed that several residues in hen egg white lysozyme could be resolved in ¹H NMR, and this was then followed by Allerhand et al. who observed a ~6 ppm range for the ¹³C chemical shift of C- γ of the six tryptophan residues in hen egg white lysozyme.² Although such chemical shift inequivalencies have made multidimensional NMR studies of proteins possible,^{3,4} understanding of the origins of such chemical shift nonequivalencies remained a very major challenge until recently, when a first-principles reproduction of the NMR spectra of the heavier nuclei (¹³C, ¹⁵N, and ¹⁹F) in proteins was demonstrated to be feasible.⁵ Here, we trace the development of NMR chemical shift interpretations in biological systems, starting from the discovery of empirical correlations between shift and structure in proteins, up to the present ab initio interpretation of protein, nucleic acid, and carbohydrate chemical shifts, and the derivation of structure from shielding.

2 EMPIRICAL SHIFT–STRUCTURE CORRELATIONS IN PROTEINS

The earliest attempts at unraveling the relationship between secondary structure and chemical shifts were focused on H- α .^{6–8} Due to the small chemical shift range and the sensitivity of ¹H shielding to not only electrostatic effects but also magnetic factors, such as ring currents and the anisotropy of the diamagnetic susceptibility of peptide groups, only general trends were found between structure and shielding.^{9,10} In contrast to ¹H NMR, the heavier nuclei exhibit a much wider chemical shift range, rendering such magnetic effects of minor importance. Hence, ¹³C and ¹⁵N nuclei offer more promise, and considerable efforts were made in interpreting these shifts as soon as they became available.

In early work, Kricheldorf et al.¹¹ and Saito et al.¹² showed that ¹³C chemical shifts in peptides were mainly influenced by the torsion angles ϕ and ψ . Theoretical attempts involving a semiempirical finite perturbation—incomplete neglect of differential overlap (FPT–INDO) method aimed at reproducing these observations were somewhat successful in demonstrating the nonequivalency between helical and sheet residues,¹³ but the calculated differences were much smaller than the range observed experimentally. With an increasing number of assigned C- α and C- β resonances in various proteins—bovine pancreatic trypsin inhibitor (BPTI), calmodulin, interleukin-1 β and staphylococcal nuclease—Spera and Bax introduced the first empirical ϕ , ψ chemical shift surface for C- α and C- β using known X-ray data,¹⁴ shown in Figures 1(a) and (b). Figure 1(c) shows histograms of the secondary shift distribution in α -helical and β -sheet residues. From the presently available database of ¹³C chemical shifts it is clear that C- α resonances of helical sites are deshielded compared with those residues which occur in sheet regions. The opposite trend is evident for C- β , where helical sites are more shielded.¹⁴ Such empirical observations have found use in the chemical shift index,¹⁵ which permits prediction of helical and sheet structure, based on C- α C- β , C^o, and H- α shifts.

Considerable attention was also given early on to ¹⁵N shifts in proteins.^{16,17} However, the problem of whether or

Figure 1 Secondary chemical shift surfaces $\Delta\delta(\phi, \psi)$ and secondary chemical shift histograms for C- α and C- β sites in proteins. (a) Empirical secondary chemical shift surface for C- α nuclei in proteins; (b) as in part (a) but for C- β ; (c) histogram showing the distribution of observed secondary shifts for C- α and C- β . (Reproduced by permission of the American Chemical Society from S. Spera and A. Bax, *J. Am. Chem. Soc.*, 1991, **113**, 5490)

not ^{15}N chemical shifts can provide information regarding local structure remained unanswered. Glushka et al. then noticed a correlation between ^{15}N chemical shifts and the torsion angle ψ_{i-1} for residues in sheet regions in BPTI and apamin, but no other structural or ‘interaction’ features were found.¹⁸ More recently, using a much larger database (consisting of 14 proteins and 1477 ^{15}N chemical shifts), Le and Oldfield¹⁹ found a better empirical correlation between the peptide ^{15}N chemical shift and the torsion angles ϕ_i and ψ_{i-1} , indicating that there is indeed a significant relationship between ^{15}N chemical shifts and secondary structure. The larger number of points permitted study of individual amino acid shift surfaces. Figures 2(a)–(c) show the agreement obtained between experimentally obtained ^{15}N chemical shifts and those derived from the empirically fitted shift surfaces, for aspartic acid, lysine, and valine. The presence of an intrinsic relationship between ^{15}N chemical shifts and secondary structure becomes evident from these studies. However, it can also be inferred that there are other factors, such as electrostatic interactions, side-chain conformation, and hydrogen bonding, which all potentially influence ^{15}N shielding. The side chain of valine, for example, introduces an additional angle χ^1 , which can modify the ^{15}N chemical shift behavior, since the presence of a substituent at the β -carbon site introduces a γ -gauche effect, as noted earlier by Tonelli.²⁰ In order to take this into account, a much larger database would be needed in order to create separate shift surfaces for each of the three common χ^1 conformers. Empirical database approaches are thus useful in indicating trends, but it would clearly be desirable to be able to predict shifts accurately using first principles or ab initio approaches. For example, the ^{15}N -valine χ^1 -torsional problem is one which can easily be solved if the torsional dependencies can be derived from first principles. As demonstrated recently, this is now possible.¹⁵ In addition, sensitivity to side-chain conformation is not exclusive to ^{15}N , since ^{13}C shifts for C- α and C- β sites are also expected to exhibit a χ^1 dependence. This, however, would be difficult to see with only a small database of assigned ^{13}C shifts. Ab initio methods therefore clearly have an advantage over empirical approaches since chemical shift surfaces for individual amino acids, as well as for various χ^1 conformers, can in principle be evaluated.

With the rapidly growing database of ^1H chemical shifts,²¹ there has been renewed interest in using ^1H NMR in protein structure studies.^{22–27} These studies have taken advantage of the availability of large numbers of ^1H chemical shifts to relate chemical shifts to structure. In addition to the correlation found between secondary structure and the chemical shifts of H- α and H-N, the large amount of spectroscopic information available has also permitted a breakdown of ^1H shielding into electrostatic and peptide magnetic anisotropy effects. Thus, the coefficients needed in order to evaluate electrostatic contributions from nearby polar groups, as well as the anisotropy effects arising from peptide bonds, have been derived empirically. The complexity and number of factors that affect ^1H chemical shifts, however, make a direct chemical shift to structure route very difficult, although structure refinement using H- α shifts has promise.³⁰

Figure 2 Correlation between experimental secondary ^{15}N chemical shifts and those computed from empirically fitted individual secondary chemical shift surfaces. 3 THE AB INITIO APPROACH TO PROTEIN SHIELDING

Although empirical and semiempirical approaches for ^1H NMR are useful for analyzing secondary structures, these approaches are more limited for the heavier nuclei. The reason for this is that long range magnetic anisotropy effects will be very small for ^{13}C and ^{15}N , due to the large ^{13}C and ^{15}N shift ranges ($\sim 8\text{--}30\text{ ppm}$). Moreover, $\text{C-}\alpha$ and $\text{C-}\beta$, being both sp^3 -hybridized carbons, are not expected to have their chemical shift greatly influenced by electrostatic factors. Thus, in order successfully to predict and interpret the chemical shift of heavy nuclei in proteins, it is desirable to apply ab initio methods. These, in general, successfully predict shielding for such heavy elements—at least for ^{13}C , ^{15}N , and ^{19}F . The system, however, consists of so many atoms that a computation which includes the whole protein would be prohibitive, even with supercomputers. Fortunately, however, since the chemical shift is inherently a localized property, it is wrong to suppose that the effects of all atoms in a protein need to be incorporated into the computation. One approach is to separate the total shielding, σ_{t} , into three parts³¹

$$\sigma_{\text{t}} = \sigma_{\text{s}} + \sigma_1 + \sigma_0 \quad (1)$$

where σ_{s} refers to the short-range contribution, σ_1 corresponds to long range electrostatic effects, and σ_0 contains the magnetic effects. Although orthogonality may not be achieved, such a partitioning of the various chemical shift contributions helps develop computational strategies for solving each contribution.

The short range contribution can be further divided into several categories: local structure, repulsive interactions, and strong hydrogen bonding. Local structure includes the dependencies of the chemical shift on bond lengths, bond angles, and torsion angles. For the long range electrostatic contributions, several methods can now be used. One can either incorporate the charge field at the self-consistent field

(SCF) level,³² or use the multipole shielding polarizability (MSP) approach.³³ Lastly, σ_0 can be calculated by a variety of classical methods, basically as discussed above for ^1H NMR. This contribution is, however, still within the error limits of present ab initio methods for calculating σ_{s} and σ_1 , although it can still be expected to help somewhat with shift predictions. For further discussions on intra- and intermolecular factors which influence shielding, several recent reviews are available.^{34,35}

Hence, for a protein, atoms belonging to the residue which contains the nucleus of interest can be regarded as contributing to σ_{s} , while the rest of the protein contributes to σ_1 . This partitioning greatly reduces the size of the fragment on which full ab initio calculations need to be performed. When combined with recent improvements in hardware (such as powerful workstations) and a method which avoids gauge errors in calculating the shielding property [the gauge-including atomic orbital (GIAO) method],³⁶ together with the application of new algorithms to improve code efficiency,³⁷ the ab initio reproduction of chemical shifts in proteins is now at hand.

In recent work,⁵ it was shown that a small molecular fragment, *N*-formyl-L-alanine amide, interacting with formamide molecules (used to represent hydrogen bond partners) and point charges (representing the rest of the protein) successfully reproduced the experimentally observed ^{13}C chemical shifts for the 12 alanine $\text{C-}\alpha$ and $\text{C-}\beta$ sites in the protein staphylococcal nuclease, as shown in Figure 3. The ability to predict the chemical shift opens up a new avenue for protein structure elucidation, especially if the factors which lead to such nonequivalencies can be identified. The partitioning of the shielding as described above greatly facilitated this quest.^{5,38} As expected, $\text{C-}\alpha$ and $\text{C-}\beta$ chemical shift nonequivalencies were found to be dominated by the local structure, or short-range factors, σ_{s} .³⁶ In addition, based upon an examination of the dependencies of $\text{C-}\alpha$ and $\text{C-}\beta$ shielding on bond lengths, bond angles, and torsion angles, it was established that torsion angles clearly dominate the experimentally observed trends. In particular, it was also noted that the chemical shifts at these

Figure 3 Comparison between calculated ^{13}C NMR shieldings and experimental chemical shifts for alanine residues in staphylococcal nuclease. (a) C- α , (b) C- β . (Reproduced by permission of the American Association for the Advancement of Science from A. C. de Dios, J. G. Pearson, and E. Oldfield, *Science*, 1993, **260**, 1491)

sites were extremely sensitive to bond lengths. In fact, the variations in bond lengths of the same type of residue seen in a single-crystal X-ray structure were shown to lead to a chemical shift range as large as the experimentally measured range, but the predicted shifts were wholly uncorrelated with experiment.³⁹ Residues of the same type in a protein therefore have bond lengths that are much more similar to each

other than X-ray structures would suggest. Nevertheless, from these same studies, ϕ - and ψ -angles were found to be highly correlated with C- α and C- β shifts. Shielding surfaces have therefore been constructed using a model fragment, *N*-formyl-L-alanine amide, in order to map out the effects of ϕ and ψ on C- α and C- β shieldings.³⁸ With this surface serving as a look-up table, and knowledge of ϕ and ψ , ^{13}C shieldings (or chemical shifts) for any alanine site in a protein can readily be obtained—at least in the absence of large-amplitude motions.

Nitrogen-15 shieldings are expected to be more difficult to predict, since well-defined ϕ and ψ correlations have not been observed, and hydrogen bonding and electrostatic effects could also be important. Recent work,⁵ however, has shown that ^{15}N chemical shifts in proteins can now be predicted using the GIAO method, with explicit hydrogen bond partners, and point charges representing the rest of the protein. Figure 4 shows results for valine residues in staphylococcal nuclease.⁵ The results in Figure 4(a) were obtained by using a molecular fragment; formyl-L-alanyl-L-valine amide. In Figure 4(b), hydrogen bond partners were explicitly included (as formamide molecules), while Figure 4(c) includes the rest of the protein, represented as point charges. Although the dominance of torsion angles found in ^{13}C chemical shifts is less dramatic with ^{15}N , the generally good accord between calculated and observed values when long range factors are included indicates that ^{15}N NMR is a potentially powerful technique for structure validation. Its sensitivity to long range interactions extends the structural information that can be obtained beyond the local torsion angles, thus complementing ^{13}C NMR.

Although not naturally occurring in most proteins, ^{19}F is a particularly sensitive probe of electrostatic field effects in proteins. Its incorporation, for example, into tryptophan residues of *Escherichia coli* galactose-binding protein (GBP)⁴⁰ and hen egg white lysozyme⁴¹ has generated information on how long range factors, such as van der Waals and electrostatic interactions, influence the chemical shift. Using point charges, GIAO has been shown⁵ to reproduce satisfactorily the observed ^{19}F NMR spectrum of 5-F-Trp-labeled GBP, except for solvent-exposed sites. With prior knowledge of how shielding is affected by a uniform electric field, field gradient, and field hypergradient (the MSP approach), dynamic averaging becomes tractable,⁵ and even shielding at sites that are highly mobile and solvent exposed can be satisfactorily reproduced.³⁹

Overall, ^{13}C chemical shifts show great promise in structure elucidation, as noted above for alanine. Successful prediction of ^{13}C chemical shifts has also been shown for glycine and valine residues.³⁹ Here, the dominance of ϕ and ψ is similarly evident. The correlation between calculated and experimental shieldings for glycine sites is less satisfactory than with alanine and valine, possibly due to glycine mobility. On the other hand, the presence of the side chain in valine introduces an additional angle that can influence both C- α and C- β shieldings. Taking advantage of this additional dependency, crystal-to-solution structural differences became apparent upon close examination of the C- α and C- β shifts of valine residues in calmodulin.⁴² Corroborated by coupling constant information, this work demonstrated that five out of the seven valine residues assume a side-chain conformation different from that seen by X-ray crystallography.

Figure 4 Calculated ^{15}N chemical shieldings versus experimental shifts for the valine sites in staphylococcal nuclease. (a) Using isolated valine fragments; (b) as in part (a) but with inclusion of a hydrogen bond partner; (c) as in part (b) but with incorporation of point charges to represent the rest of the protein. Finally, we briefly consider shielding as a tensor quantity. Here, all elements and their directions need to be evaluated—six parameters versus one isotropic shift, representing a serious challenge for theory. For amino acid crystals, the charge field perturbation gauge including atomic orbital (CFP-GIAO) method gives excellent agreement with

experiment.⁴³ Figure 5 shows a comparison between calculated and experimental shielding components for the ^{13}C nuclei in L-threonine⁴³ in the icosahedral representation⁴⁴ of the shielding tensor. The results shown here clearly illustrate the adequacy of present theoretical methods of predicting chemical shieldings, even in complex (zwitterionic, polar amino acid) systems.

4 NUCLEIC ACIDS

The usefulness of chemical shifts in studying biological systems is naturally not restricted to proteins. Chemical shifts of nucleic acids should similarly encode a wealth of information regarding structure, protonation sites, hydrogen bonding, and electrostatic field effects. The shielding caused by magnetic anisotropy effects on ^1H NMR spectra has already been studied using semiempirical methods,⁴⁵ and more recently *ab initio* methods have been used to study the pyrimidine base cytosine.⁴⁶ However, these early results were obtained using only a split valence set, insufficiently saturated with basis functions. A more recent study using a larger basis was performed by Schindler⁴⁷ using the individual gauge for localized molecular orbitals (IGLO) method.⁴⁸ The shielding tensors, as well as the magnetic susceptibilities, were calculated for cytosine, thymine, and uracil, as well as adenine and guanine. The calculated values compared favorably with experiment, but in general the computation of shielding tensors in nucleic acid bases is difficult because definite molecular structures that correspond to the systems on which the NMR measurements were taken are usually not available. In particular, the relative amounts of tautomers depend strongly on the solvent and pH, and the ^{15}N chemical shifts were found to be very sensitive to such environmental effects. Nevertheless, using *ab initio* optimized structures, it was shown that the calculated ^{15}N shielding trends caused by

protonation could indicate which species dominate in solution. However, the lack of a supportive trend from ^{13}C shieldings did not permit a more precise determination of the dominant tautomer.

5 CARBOHYDRATES

With the importance of carbohydrates in lipid and (glyco)protein structure, as well as in, for example, substrate/inhibitor binding (e.g. in lysozyme), and the occurrence of carbohydrates in metabolism, cell surface antigens, etc., it is surprising that so little work has been reported on ^{13}C and ^{17}O NMR shielding, at the ab initio level. An exception to this is the pioneering work of Grant et al.⁴⁹ on ^{13}C shieldings in methyl α -D-glycopyranoside and sucrose. Grant et al. showed that a root mean square deviation (rmsd) of ~ 3 ppm between theory and experiment (the rmsd from the straight line connecting shift and shielding) with $R^2 \sim 0.97$ and a slope of -0.99 (methyl glucoside), could be obtained at the 6-31G level, permitting a convincing reassignment of some earlier chemical shift assignments.

6 STRUCTURE FROM SHIELDING: PREDICTION, REFINEMENT, AND VALIDATION

The ability to predict the NMR spectra of biologically important molecules via ab initio methods heralds a new era in the use of the easiest NMR parameter to measure, the isotropic chemical shift. For proteins, the intimate relationship found between the torsion angles ϕ and ψ and the ^{13}C chemical shifts of C- α and C- β sites strongly suggests that it should be possible to derive structural information from chemical shifts in ways not founded on empirical relationships, size of database, or on X-ray structures. One such method of extracting torsion angles from spectroscopic parameters has recently been proposed.⁴⁸ Referred to simply as the 'Z-surface method', it begins with the assumption that a given spectroscopic parameter, P , can be represented as a function of a torsion angle α

$$P = f(\alpha) \quad (2)$$

and the probability that a given value P_i corresponds to a value of α can be cast as in

$$Z_i = \exp[-(P_i - f(\alpha))^2 / W] \quad (3)$$

W is a search width of typically about 1 ppm, and takes into account uncertainties in theoretical and experimental results, e.g. basis deficiencies, referencing errors, etc. Equation (3), of course, assumes a knowledge of $f(\alpha)$, which can be obtained via ab initio methods or from experiment. A plot of Z_i over possible values of α constitutes a probability surface for the angle α . Since the chemical shifts of C- α and C- β are both functions of torsion angles ϕ and ψ , a map of the whole Ramachandran space that shows which pair of ϕ - and ψ -angles closely agree with the observed chemical shifts can be easily constructed. For alanine residues in a variety of proteins, using this approach and the theoretical shielding surfaces for C- α and

C- β , plus an experimental surface for H- α , yields values for ϕ and ψ that have only $\sim 10^\circ$ rmsd values from the X-ray values.⁵⁰

Although ^{15}N chemical shifts are more susceptible to environmental effects, and ^{19}F shift inequivalencies are largely due to electrostatic interactions, this sensitivity of the ^{19}F and ^{15}N shieldings to electrostatic interactions can be utilized in testing present force fields, molecular dynamics programs, and electrostatic field calculations.⁵¹ Moreover, ^{15}N being sensitive to factors other than local structure, it can complement ^{13}C NMR in validating the overall structure of a protein.

7 CONCLUSIONS

Chemical shifts have been reported in biochemical systems for about 30 years. However, only very recently has it been possible to solve the chemical shift problem, and successfully predict chemical shifts in macromolecules, such as proteins.⁵ Since chemical shifts can now be intimately related to structure, and vice versa, it seems likely that many new applications to structure prediction, refinement, and validation will stem from these developments. Until recently, it was thought by many to be impossible to predict protein chemical shifts. However, the continuing revolution in computer/disk price/performance ratios now enables study of much larger fragments than heretofore possible. In the future, we believe that many such applications of 'biochemical shifts' and quantum chemistry will contribute greatly to our studies of lipid, protein, nucleic acid, and carbohydrate structure.

1 INTRODUCTION

This article concentrates on chemical shifts in nucleic acids as indicators of conformation. Shifts of ^1H , ^{13}C , and ^{15}N are reviewed. A complete treatment of ^{31}P shifts is given elsewhere by Gorenstein (see *Nucleic Acids: Phosphorus-31 NMR*), as is the characterization of unusual bases by Agris (see *RNA Structure and Function: Modified Nucleosides*). The nomenclature used is that of Saenger.¹ In this short article, it is not possible to review the whole subject, so emphasis is placed on areas of major impact, without attempt to be comprehensive or to apply historical credit.

Nucleic acid structures in solution continue to be a major research topic, because of both general chemical interest and the burgeoning industry of understanding the detailed interactions of nucleic acids in biological processes. Two examples of special interest are how proteins and nucleic acids recognize each other and whether there are general rules, and how some ribonucleic acids (RNAs) achieve catalytic activities. The use of chemical shifts continues to be of importance because the structures of many nucleic acids are dynamic and polymorphic. Shift analysis can attempt to achieve the simple objective of defining whether there is predominantly a single structure (or small family) to be analyzed, and can, in favorable cases, achieve the more complex objective of a reasonable level of secondary structural information. To address the more complex biological areas, higher molecular weight complexes require study, since the structures of the nucleic acid components alone rarely provide any clear perspective on the mode of binding and interaction, as vividly illustrated in the dramatic twisting of the deoxyribonucleic acid (DNA) strands in complexes with Transcriptional Binding Protein (TBP)² a result entirely unanticipated from solution studies of the DNA oligomers alone. Higher molecular weight complexes, often with proteins or other nonnucleic acid components, have extensively overlapped spectra, so the additional dispersion from the use of heteronuclei and multidimensional NMR becomes imperative.

2 DNA OLIGOMERS

The naming of atom positions in the bases and in deoxyribose are shown in Figure 1, which also illustrates the base pairing expected in the Watson–Crick form. In this form, imino and amino hydrogens have reduced rates of exchange with solvent hydrogen, and so the appearance of these normally exchangeable hydrogens in the spectrum is diagnostic of base pairing. The observation of well-resolved imino resonances of comparable width and intensity to nonexchangeable hydrogen resonances then provides definitive evidence for a single well-defined structure. Successful structural investigations appear to rely heavily on this characteristic to find conditions of temperature, pH, cations, etc., favorable to the determination.

Standard procedures exist for assignment of most exchangeable^{3,4} and nonexchangeable hydrogens.^{5–8} The shifts of nonexchangeable hydrogens in B type DNA have been thoroughly analyzed in over 600 nucleotides. The shifts of H-2', H-2'', H-3', H-4' and H-6/H-8 are dominated by the identity of the attached base. Cytidine (C) H-5 and thymine (T) CH₃ are influenced by the adjacent 5' base, while H-1' is influenced by the adjacent 3' base. The averaged values and their distribution profiles are for oligonucleotides observed under fairly wide solution conditions and temperatures, so highly precise reference values are probably best obtained by using those from a closely related sequence under similar solution and temperature conditions.⁵

Shifts outside the normal ranges can be used as preliminary identification of sites of binding or modification. For example, the shifts of base and sugar H-1' in a modified duplex with benzopyrene diol epoxide have been used as supporting evidence for the stacking of the benzopyrene ring directly over the sugar of one base in the minor groove.⁹ In closely analogous sequences, similarities of many shifts of the unchanged residues can then be used to infer similarity of structure. For example, the base and 2',2'' shift of an A₃ bulge (A = adenosine) from a duplex are virtually identical to those in an AIA bulge (I = inosine), when the I substitution is used to separate otherwise isochronous A H-8 signals for the purposes of sequential assignment by COSY and NOESY.¹⁰

3 ^{13}C AND ^{15}N SHIFTS

The extension of these uses of shifts of hydrogens to other nuclei was a natural development, impeded by the difficulties of synthetic incorporation of stable isotope labels, and/or by low NMR sensitivity. Incorporation of labels still remains very expensive, and for DNA the precursor deoxynucleotides present difficulties. Labeling of RNA has become practical and efficient for designed sequences,^{11,12} and transfer RNAs have been biosynthetically labeled for assignment purposes for many years. Indirect detection methods, and their elaboration into methods for connectivity determination using multidimensional NMR,¹³ have similarly alleviated sensitivity issues. Indirect detection methods have made it practical to observe ^{13}C and ^{15}N shifts without enrichment, and these have provided, complementarily to earlier studies with short oligonucleotides,¹⁴ an adequate base for assignment and interpretation for DNA oligomers.^{15–17} For example, for ^{13}C shifts, purine C-2 resonances are sufficiently separated from purine C-8 and pyrimidine C-6 resonances, that the overlap in the hydrogen spectra of the appropriate H2, H8, and H6 resonances can be partially resolved by inspection. Similarly, H1' and pyrimidine H5 can be type assigned by two-dimensional (2D) separation of the C-1' and C5 resonances, and H3', H4', H5', and H5'' are separable also. Purine C-8 can be discriminated from pyrimidine C6 by the C8s larger $^1J(^{13}\text{C},^1\text{H})$ value in coupled spectra. For ^{15}N parameters, in the critical imino area, pyrimidine N3 and purine N1 are separated by about 10 ppm, permitting considerable additional resolution of the imino hydrogens in a $^{15}\text{N}/^1\text{H}$ 2D map. These experiments are still relatively little used, despite their clear and rich information content.^{18–20}

4 TEMPERATURE DEPENDENCE OF ^{13}C SHIFTS

The profiles of chemical shifts with temperature have received considerable attention, especially those for hydrogen. This approach provides a potential avenue to understanding the contributions of individual components to the melting phenomena, in contrast to the bulk properties observed by ultraviolet absorption or circular dichroism. The interpretation of the changes of shifts observed has not proved to be entirely simple, and increasingly elaborate models have been used.²¹ Variable temperature studies using ^{13}C have been more limited. This is in spite of the potential for using relaxation dynamics, or the effects of pseudorotation of the ribose ring on shifts.²² Detailed temperature profiles of a small number of oligomers are available for base¹⁶ and sugar²² carbons. These provide a highly detailed grounding from which to consider the origin of shifts in oligonucleotides.

The observations for bases may be summarized as follows. A range of shifts of about 3 ppm for each class of carbon in the low-temperature duplex narrows to <1 ppm range at high temperature. Residues at the termini show smaller transitions than others. The slopes of $d\delta/dT$ are mixed (positive, negative, around zero), with most showing the largest change at around the melting temperature, but with clear evidence for one or more 'pretransitions' below that temperature, especially at carbons at guanosine G2, G6, and T4. There is essentially no obvious neighboring dependence for each pair of base types.

Detailed quantum mechanical calculations of the shifts for bases^{23,24} and sugars²⁵ are available. Naturally, the match of experiment and theory will be limited by neglect of conformation averaging, of solvation, and by the limited orbital sets used. For bases, the melting effects have been summarized¹⁶ as arising from changes in hydrogen bonding, both that to a partner base and that to solvent, from base stacking effects, and from steric compression. Hydrogen bond related changes occur on those carbons adjacent to a nitrogen or carbonyl participating in hydrogen bonding. Since those sites may be involved in hydrogen bonding with other bases, or with solvent water, changes are then the summation of multiple effects depending on the relative strengths of the different hydrogen bonds involved. The expectation is then that substantial negative $d\delta/dT$ values should be seen for C2 and 6 in G, and 4 in T, with lesser effects at 2, 5, and 6 in A, and 2, 4, 5, and 6 in C. Base stacking effects are similarly complex in effect, and it may be concluded that a geometric effect similar to a ring current shift would be expected to produce a positive $d\delta/dT$ going from a stacked to a single-stranded form. It seems unlikely that steric compression effects could play a major role in shifts in such duplexes, where there are considerable degrees of backbone freedom.¹ The most reasonable hypothesis concerning the temperature dependence of base shifts then centers on the cooperative transition of melting changing simultaneously the oppositely signed contributions of geometric stacking and of hydrogen bonding. The individual changes then reflect the different roles of each carbon with respect to the geometry of the stacking, or the adjacency to a hydrogen bonding site. A plausible hypothesis for the premelting changes is that there is apparent weakening of the hydrogen bonding prior to the principal transition.

In the case of deoxyribose sugars,²² the temperature dependence of carbon shifts might be expected to shed light on the much discussed issue of pseudorotation in the sugar ring. Early work²⁶ suggested that fitting the observed vicinal coupling constants in deoxyribosides needed at least a two-state model, incorporating the 'N' (North), 3'-endo, or 'S' (South), 2'-endo conformers of the ring.¹ This is now generally,²⁷ though not universally,^{28,29} accepted for oligonucleotide analysis also, with the caveat that other sugar puckers may be significantly populated, but cannot be easily experimentally analyzed, so Occam's razor reduces us to using the simplest model.²⁷ This and other issues^{30,31} continue to point out possible limitations of high-precision attempts to determine DNA oligomer using single conformer models. Sugar ^{13}C shifts might be a useful additional characteristic of ring pucker, and this has been established for some RNA oligonucleotides,^{20,32} in a relatively straightforward way. Detailed studies of DNA oligomers do not support this kind of analysis, and deviations of shifts with respect to temperature show quite different patterns.²² A general explanation is that indeed multiple ring conformers do exist, and that the deoxyribose and ribose rings naturally have different sets of conformers. The general magnitude of the alteration of shift with melting is, however, quite small (about 1–2 ppm), so it is very difficult to make a complete differentiation of shift effects arising solely through ring conformation, from those arising from ring current (magnetic anisotropy) and other more distant effects. In general, the conclusion that these melting curves require a more complex explanation than an S–N conversion

alone is fully justified, and more detailed studies of the effects of sequence seem appropriate.

5 ISSUES WITH RNA

Spectral assignment in RNA had previously been difficult, because of the overlap of sugar hydrogens in the 4–5 ppm region. Resolution by multidimensional heteronuclear shift correlation with ^{13}C provides a straightforward additional dispersion, with C-5', C-3', C-2', C-4', and C-1' being ordered in increasing shift in relatively well-separated groups.³³ It remains to be seen, in the large structural variations of bulges, internal loop, duplexes, and hairpins, whether these simple classifications will suffice. The success of a multidimensional, triple resonance approach using $^{13}\text{C}/^{15}\text{N}$ dual-labeled duplex dodecamer,³⁴ bodes well for complete assignment of significantly larger RNAs. This approach similarly depends on the large ^{13}C dispersion to separate out sugar hydrogens.

Using the characteristic imino hydrogen region, several laboratories made remarkable progress in assigning larger RNAs, especially transfer RNAs and 5S RNA. Additional information from ^{15}N shifts has also been widely used, mainly for group-specific assignments.

6 ^{15}N SITES AS STRUCTURAL INDICATORS

It will be readily apparent by inspection of Figure 1, that nitrogens are potentially reporters at the sites of the major interactions of the bases. They participate in the Watson–Crick hydrogen bonding (C,3,4; G,1,2; T,3; and A,1,6), serving as donor in all cases, and recipient at C3 and A1. The major groove of a double helix is also lined with the amino groups of A and C, and the nitrogen at position 7 in purines A and G, while the purine position 3 is exposed in the minor groove. The known perturbations of shifts on hydrogen bonding, for donor or recipient, then provide a specific window into the major recognition elements of the bases. This simple reporting may be invaluable in larger complexes where full determination of structure is presently impractical. Some existing studies include the investigation of Hoogsteen hydrogen bonding in triple helices¹⁹ and guanine tetrads,³⁵ investigations of the effects of *O*-methylation,^{36,37} and studies of netropsin/duplex complexes.^{17,38}

DNA triplexes can be readily formed by appropriate sequences in which a purine-rich tract makes Watson–Crick contacts with a pyrimidine-rich strand, and then a subsequent pyrimidine-rich strand make predominantly Hoogsteen pairing to the central purine-rich portion, and the Watson–Crick pairing is readily apparent in the shifts of G1 and T3 nitrogens.¹⁹ In guanine-rich tetrads, the shift variation between duplex, tetrad, and single strand forms for the N-7 of G in two sequences was found to be rather small, and while hydration effects and hydrogen bonding may be usefully investigated in lower molecular weight complexes,³⁵ the prospects for use in larger complexes are not clear.

Several oligomers containing $[1'-^{15}\text{N}]$ - and $[2-^{15}\text{N}]\text{-O}^6\text{-methyl-2'-deoxyguanosine}$ have been studied, confirming expected base pairings in mismatches against C and T. These

studies elegantly illustrate the positional specificity available from NMR studies for base–base hydrogen bonding and for the pH and temperature dependence of such bonding. For the O^6MeGT pair, there is direct hydrogen bonding at N-2 but not N-1, with N-1 probably fully solvated.³⁶ In contrast, the O^6MeGC pair has a very complex, pH-dependent, wobble pairing.³⁷ The low-frequency melting shift of the $[1-^{15}\text{N}]\text{O}^6\text{MeGC}$ resonance (3 ppm) is similar to that for other hydrogen bond acceptors, whereas the high-frequency shift of $[2-^{15}\text{N}]\text{O}^6\text{MeGC}$ (8 ppm) is not similarly matched. This is in line with expected differences in hydrogen bond strength: the apparent high-frequency shift of an $\text{O}^6\text{MeG } ^{15}\text{N}2$ as an sp^3 hydrogen bond donor to an sp^2 nitrogen acceptor is significantly greater than that associated with $\text{NH}_2\text{--O}$ interaction.

The structures of netropsin/DNA oligomer complexes have been extensively studied by X-ray and NMR methods. Nitrogen-15 studies are fully consistent with the general view that netropsin displaces water of hydration from the minor groove, without significant perturbation of the duplex structure. Shifts from positions 3 in A,³⁸ 1 in G, and 3 in T¹⁷ are all indicative of modulated hydrogen bonding on complexation at the expected positions. The suggestion¹⁷ that larger perturbations of 3 in T result from the alterations of the adjacent carbonyl's hydrogen bonding indicates a possible sensor of the critical pyrimidine 2-position in the minor groove, but requires further experimental support.

7 CONCLUSIONS

The major motivation for continuing interest in this area is the need for better tools to study macromolecular interactions involving larger pieces of nucleic acids than are currently normally studied. Shifts on formation of DNA–protein complexes have been reported for several cases.^{39–41} In general, these shifts are interpretable using the same rationales, interrelation, major or minor groove binding, disruption of pairing and/or stacking, and possible displacement of water, and it may be expected that their extension with ^{13}C and ^{15}N labeled nucleic acid components would be invaluable. Continuing efforts in rationalizing the observed shift effects then also remain a priority.

1 INTRODUCTION

^{17}O is the least utilized of the NMR active nuclei commonly found in biological systems. While oxygen atoms play an important role in the hydrogen bonding, electrostatics, and hydration of biomolecules, the very low natural abundance (0.037%) and quadrupolar nature ($I = \frac{5}{2}$) of ^{17}O nuclei have hindered the development of ^{17}O NMR as compared with ^1H , ^{13}C , ^{15}N , and ^{31}P NMR in biological systems. Over the last decade, however, the availability of both ^{17}O enriched materials and ever higher field FT NMR spectrometers have led to the utilization of ^{17}O nuclei as probes of biomolecular structure and function, some 40 years after the nucleus was first observed.¹

It is the intention of this article to review the characteristic parameters governing the use of ^{17}O NMR in, and how the behavior of ^{17}O nuclear spin magnetization has been applied to, biological systems. The effects of ^{17}O quadrupolar relaxation on ^{31}P magnetization are also important, but are beyond the scope of this review.

2 ^{17}O NMR PARAMETERS

The detailed quantum chemical description of sites in biologically relevant molecules is, in general, extremely complex. The task is greatly simplified in NMR by modeling nuclear spin interactions as independent of the rest of the system, with time-dependent interactions between spins and the bulk (or lattice) being termed ‘relaxation’. This, and other considerations, allows for the simplification of the ^{17}O NMR of biomolecules to the study of ^{17}O chemical shielding, ^{17}O relaxation (resulting from couplings between the nuclear quadrupole and its local environment), and ^{17}O quadrupole couplings.

The chemical shielding of a nucleus is a function of the electronic structure near the nucleus. ^{17}O nuclei are particularly sensitive to differences in chemical environment;

for example, the two distinct oxygen sites in ozone are separated by 566 ppm.² Differences in chemical shift between sites in a molecule can be used to determine molecular structures, as well as to study dynamical processes in these structures, such as conformational changes, substrate binding, and hydrogen bonding. The ^{17}O chemical shift is commonly referenced to H_2^{17}O in biological NMR studies.

All nuclei with $I > \frac{1}{2}$ have a nuclear quadrupole moment eQ . The interaction of eQ with an electric field gradient eq is quite strong, typically dominating the NMR spectrum of a quadrupolar nucleus. For most biomolecules, the interaction between the eQ of ^{17}O and eq is modulated by rotational motion, either molecular tumbling or internal rotations, making it an efficient relaxation mechanism. In the extreme narrowing limit (very fast motions on the NMR timescale), the nuclear quadrupole relaxation rate essentially determines the resonance linewidth L which can be expressed as

$$L \approx (12\pi/125)(1 + \eta^2/3)\chi^2\tau_r \quad (1)$$

where $\chi = e^2qQ/h$ is the nuclear quadrupole coupling constant, η is the asymmetry parameter of the electric field gradient tensor, and τ_r is the rotational correlation time.³ ^{17}O linewidths are therefore proportional to the square of the electric field gradient at the nucleus, and are generally inversely proportional to the molecular correlation time. This limits the applicability of ^{17}O NMR either to relatively small molecules or to sites in molecules where χ is much less than typically found for ^{17}O nuclei (about 10 MHz, see Kintzinger⁴). Within this limitation, ^{17}O relaxation can be used to measure differences in χ and τ_r for either two sites in the same molecule, or the same site under different conditions. For slow molecular motions ($\tau_r \gg 1/\nu_L$) relaxation is a weighted sum of three exponentials, resulting in deviations from Lorentzian lineshapes, and such effects have been observed experimentally for C^{17}O bound to heme proteins, where χ values are very small (about 1–2 MHz).⁵

3 BIOPHOSPHATES

Biophosphates are involved in many biological processes, such as energy transport and utilization, information storage and retrieval, and membrane structure and transport. Examples of such compounds are adenosine diphosphate (ADP), adenosine triphosphate (ATP), DNA, RNA, and phospholipids.

Tsai et al.⁶ have demonstrated that bridging and phosphoryl ^{17}O resonances in biophosphates can be assigned from their relative linewidths, due to differences in χ between the various sites. Linewidths are all relatively broad, and several groups have demonstrated improved spectral resolution upon sample heating,^{7–11} which decreases τ_r and thereby the ^{17}O linewidths, allowing for more accurate determination of ^{17}O chemical shifts and spin–spin coupling constants, $J(^{31}\text{P}, ^{17}\text{O})$. Gerotheranassis and Sheppard¹¹ also demonstrated the utility of using ^{17}O depleted water to minimize the background H_2^{17}O solvent peak, which in aqueous samples frequently overwhelms the resonance from even an ^{17}O enriched sample.

The pH dependence of the ^{17}O chemical shift has been determined for phosphoryl oxygen atoms in several phosphates, including adenosine monophosphate (AMP), ADP, and

ATP,^{9,10} demonstrating the effect of protonation upon the phosphoryl ¹⁷O chemical shift.

The binding of several diamagnetic ions to ATP has been studied using ¹⁷O relaxation rates.^{12,13} The phosphoryl ¹⁷O linewidth increases markedly upon ion binding, indicating the coordination sites for Mg(II), Co(III), Sc(III), La(III), and Lu(III) in M · ATP_n complexes.

The hydrogen bonding of uridine derivatives has been studied using ¹⁷O NMR.¹⁴ Equilibrium constants and interaction enthalpies of water–uridine hydrogen bond complexes were determined by observing changes in ¹⁷O chemical shift as a function of water concentration, in acetonitrile.

¹⁷O spectra of hemiacetal and aldehydic abasic sites in DNA of importance in DNA damage and repair have been studied,¹⁵ demonstrating the ability to observe approximately 10 μM aldehyde signals in the presence of approximately 20 M solvent ¹⁷O.

4 AMINO ACIDS AND POLYPEPTIDES

The tertiary structures of polypeptides and proteins in aqueous solution are strongly influenced by hydrogen bonding, both within the solute molecule and with the solvent, and ¹⁷O NMR has been used to gain insights into these interactions.

The effects of proton exchange between peptide termini and water on ¹⁷O chemical shifts have been used to probe the electronic structures of amino acids,^{11,16} dipeptides,^{17,18} and peptide carboxamides.¹⁹ The ¹⁷O chemical shift has also been used to monitor the presence of hydrogen bonding in peptide models,²⁰ dipeptides,¹⁸ peptide carboxamide,¹⁹ acylprolines (model β- and γ-turns),^{21–23} and small polypeptides.²⁴

The hydration and aggregation of peptides has been studied using ¹⁷O relaxation measurements. ¹⁷O linewidths of amino acids,^{16,25} dipeptides,¹⁸ peptide carboxamides,¹⁹ and small polypeptides²⁴ have been determined in various solvents, locating hydration sites at carboxylate and carbonyl oxygen atoms, in addition to providing a method of monitoring peptide aggregation. In addition, a ¹⁷O relaxation study of ATP binding to adenylate kinase²⁶ has been reported, demonstrating the feasibility of studying enzyme–substrate interactions via ¹⁷O NMR, providing the ligand is not rigidly held.

¹⁷O chemical shifts have also been found to be torsion-angle dependent in aryl carboxylic esters, acids, and amides,²⁷ and ¹⁷O NMR promises to be a powerful technique for elucidating the structures of membrane peptides and proteins, using oriented samples.

5 CO AND O₂ IN HEMOPROTEINS

The nature of Fe–O₂ and Fe–CO bonding in heme proteins and model compounds has been studied using ¹⁷O NMR. ¹⁷O resonance frequencies and linewidths have been measured for O₂ bound to Vaska's compound,²⁸ O₂ bound to picket-fence and basket-handle porphyrin model compounds,^{29–31} CO bound to peroxidases,³² as well as other hemoproteins,^{5,33} and O₂ bound to hemoproteins in the solid state.³¹ Results were found to be in general agreement with Pauling's ideas of end-on bonding, with additional electrostatic field effects being proposed to take into account the chemical shift variation seen

from protein to protein.³⁴ In Fe–O₂ systems, the chemical shift difference between the two oxygen nuclei has been found to be about 600 ppm,^{29–31} comparable to that found in ozone, consistent with previous analogies between FeO₂ bonding and that found in O₃.

6 SUMMARY AND PROSPECTS

Given the central importance of oxygen in biochemical systems (lipids, proteins, nucleic acids and carbohydrates), there have been remarkably few studies of ¹⁷O NMR chemical shifts, and even fewer studies aimed at detailed, quantum chemical analyses of chemical shifts and quadrupolar couplings. ¹⁷O NMR in biochemistry is therefore still in its infancy. However, with the advent of 750 MHz spectrometers, the current development of 900–1000 MHz machines, as well as recent development in quantum chemical applications to macromolecules,³⁵ ¹⁷O NMR can be expected to benefit enormously over the next few years. Thus, ¹⁷O chemical shifts and quadrupole couplings can be exploited to analyze, for example, lipid headgroup and backbone orientations in membranes, sterol orientations and interactions, peptide/protein structures in condensed phases, carbohydrate conformations and interactions, as well as small DNA structures. For ¹⁷O, only relatively low resolution magnets are required, thus the sensitivity gains possible with very high-field operation can be readily exploited. Indeed, most ¹⁷O NMR studies of biochemical systems reported to date could have been obtained at about 1 ppm resolution only. With recent improvements in computer price/performance ratios, and much more efficient algorithms, theoretical analyses of ¹⁷O shifts and χ values are also to be expected. Thus, ¹⁷O NMR in biochemistry undoubtedly has an extremely bright future.

1 INTRODUCTION

The discovery¹ that the vicinal (three-bond) proton–proton coupling constant, $^3J(\text{H,H})$, varies smoothly with the associated H–C–C–H torsion angle $\phi(\text{HH})$ in ethane had a profound impact on the acceptance of NMR as an indispensable tool in stereochemistry and conformational analysis. The well-known Karplus equation,^{1,2} also called the cosine-square rule [equation (1)], was derived from valence bond calculations on the unperturbed ethane molecule.

$$^3J(\text{H,H}) = C_0 + C_1 \cos(\phi_{\text{HH}}) + C_2 \cos(2\phi_{\text{HH}}) \quad (1a)$$

The Fourier series embodied in equation (1) is more often written as:

$$^3J(\text{H,H}) = A \cos^2(\phi_{\text{HH}}) + B \cos(\phi_{\text{HH}}) + C \quad (1b)$$

Of course, simple relationships exist between C_0 , C_1 , C_2 and A , B , C , respectively: $C_0 = 0.5A + C$, $C_1 = B$, $C_2 = 0.5A$. Karplus² predicted that $^3J(\text{H,H})$ depends on various other molecular parameters, such as the electronegativity of the substituents, bond lengths, and bond angles. In the same paper² he issued a caveat against the indiscriminate application of his equation and the theoretically derived parameters [coefficients in equation (1)] to ‘estimate torsion angles to an accuracy of one or two degrees’.

The general shape of the Karplus curve, large 3J at $\phi = 0^\circ$ (eclipsed, *sp*) and at or near $\phi = 180^\circ$ (*trans*, *anti* or *ap*), and decreasing to a minimum value ($^3J \approx 0 \text{ Hz}$) near $\phi = 90^\circ$, in the course of time was shown to be applicable to many molecular fragments, including $^3J(\text{H,H})$ with heteroatoms in the coupling path and also $^3J(\text{X,H})$ and $^3J(\text{X,Y})$ with X,Y NMR-active heteronuclei like ^{13}C , ^{15}N , and ^{31}P , for example $^3J(\text{H,C,O,H})$, $^3J(\text{H,N,C,H})$, $^3J(\text{N,C,C,H})$, $^3J(\text{C,C,C,H})$, $^3J(\text{H,C,O,P})$, $^3J(\text{C,C,O,P})$. Several of these more exotic vicinal couplings are useful in the conformational analysis of bio-molecules such as peptides, proteins, nucleic acids, and polysaccharides.

In suitable cases direct (1J) and geminal (2J) coupling constants provide additional structural information, albeit of a more qualitative nature. Long-range couplings (nJ , $n > 3$) are often highly useful, especially 4J couplings (planar W path). However, the present contribution focuses entirely on vicinal (3J) couplings.

The coupling constant $^3J(\text{H,C,C,H})$ with C saturated carbon is by far the best investigated and will be treated in depth in the present article. A selection of more simple Karplus equations involving heteroatoms will be presented and briefly discussed. Familiarity with the basic tenets and methods of conformational analysis is assumed. The multitude of techniques that are currently available to measure the coupling constants of interest remain outside the scope of the present contribution (see Section 7 for related articles). Clearly, the approaches that are found useful in the conformational analysis of biomolecules are applicable to many other molecular fragments in organic chemistry. The article concludes with some applications in the field of (poly)peptides and nucleic acids, and caveats are issued. The reader is advised to consult the selection of references given for further details and for references therein.

2 VICINAL PROTON–PROTON COUPLING CONSTANTS $^3J(\text{H,C,C,H})$

2.1 General Background

In the late 1950s experiments already showed³ that the *time-averaged* $^3J(\text{H,H})$ [equation (2)] in monosubstituted ethanes $\text{CH}_3\text{CH}_2\text{X}$ decreases more or less linearly with increasing electronegativity of the substituent X.

$$\langle ^3J(\text{H,H}) \rangle = [J(60) + J(180) + J(300)]/3 \quad (2)$$

Studies carried out in the early 1960s^{4,5} confirmed these findings. Perhaps unfortunately, the (erroneous) notion that $^3J(\text{H,H})$ in all situations decreases with increasing electronegativity became firmly lodged in the minds of NMR spectroscopists. A second, also erroneous, assumption was generally accepted and that is the linear additivity of (relative) electronegativities $\Delta\chi_1 = \chi_i - \chi_{\text{H}}$. In other words, the general validity of equation (3) was accepted without question, although proper analysis of the experimental data on monosubstituted ethanes and 2-substituted propanes, already available in the early 1960s, could have shown differently.

$$^3J(\text{H,H}) = f(\phi) + a \sum_i \Delta\chi_i \quad (3a)$$

or alternatively:

$$^3J(\text{H,H}) = f(\phi)[1 - a(\sum_i \Delta\chi_i)/f(\phi)] \quad (3b)$$

where $f(\phi)$ denotes a Karplus function of ϕ_{HH} ; $a/f(\phi)$ is usually written as k .

In the case of coupling to the fast-rotating methyl protons, for example in substituted ethanes and 2-substituted propanes [equation (2)], the ϕ -dependent terms in equation (1a) vanish and $f(\phi)$ reduces to the ‘constant’ C_0 . The following comparison is obtained (Hz):

$$\begin{aligned}\text{CH}_3\text{CH}_2\text{X} :^3 C_0 = 7.5, a = -0.4 \\ \text{CH}_3\text{CH}_2\text{X} :^4 C_0 = 7.9, a = -0.7 \\ \text{CH}_3\text{CHXCH}_3 :^3 C_0 = 7.0, a = -0.55 \\ \text{Combined} :^5 C_0 = 7.7, a = -0.80\end{aligned}$$

In the remainder of this article the slope (a) will be denoted C_{01} . The ‘goodness of fit’ of these least-squares regressions (± 0.3 Hz) is disappointing, moreover, several workers^{4,5} noted a breakdown of linearity in cases where X and Y in CH_3CHXY represent highly electronegative substituents like fluorine or oxygen. It should be noted that the measured coupling to methyl cannot yield the electronegativity dependence of the ‘constants’ C_1 and C_2 in equation (1); it was simply assumed that these dependences were all equal.

In 1965 Booth⁶ noted that an electronegative substituent located on the C–C fragment constituting the coupling path and in antiparallel (*ap*) position relative to one of the two coupling *gauche* (*sc*) protons causes an ‘extra’ diminution of their mutual coupling constant (Booth’s rule). In hindsight it is easy to see that this observation implies a breakdown of the symmetry inherent to a Fourier series with cosine terms only, e.g., equation (1a), but it was not so interpreted at the time. On the contrary, one might say, and for a long time the Durette–Horton equation⁷ [equation (4)], was popular in the field.

$$^3J(\text{H,H}) = [C_0 + C_1 \cos(\phi) + C_2 \cos(2\phi)](1 - k \sum_i \Delta\chi_i) \quad (4)$$

Equation (4) is simply a combination of equations (1a) and (3b), rewritten here in terms of cosine Fourier coefficients C ; ϕ denotes the torsion angle between the coupling nuclei indicated in parentheses on the left-hand side of equation (4), $\Delta\chi_i$ are relative electronegativities of substituents according to either the Pauling⁸ or the Huggins⁹ scale.

Unfortunately, equation (4) embodies at least four questionable or even erroneous assumptions:

1. The orientation of any electronegative substituent with respect to the coupling protons is unimportant (in negation of Booth’s rule).
2. Coefficients C_0 , C_1 , C_2 have the same electronegativity dependence.
3. Substituent effects are linearly additive.
4. The standard atomic electronegativity scales^{8,9} can be applied to polyvalent substituents, regardless of the remaining atoms or groups attached.

At this point it should be mentioned that many workers in the field of stereochemistry in a way circumvented assumptions 2, 3, and 4 by the calibration of Karplus parameters for given classes of molecules of interest with the aid of model compounds with known or estimated torsion angles. Even today this approach often remains the only sensible course of action available in the case of couplings to heteronuclei, e.g., $^3J(\text{C,H})$, $^3J(\text{N,H})$, $^3J(\text{P,H})$, $^3J(\text{P,C})$, vide infra. More refined approaches are now possible in the case of $^3J(\text{H,H})$ in $\text{sp}^3\text{--sp}^3$ H–C–C–H fragments.

2.2 Substituent-Induced Asymmetry in the Karplus Curve

The first systematic investigation into the orientational effects of substituents on $^3J(\text{H,H})$ was carried out by Abraham

Figure 1 Newman projections along the central bond of a $\text{H}_\text{A}\text{--C--C--H}_\text{B}$ fragment, H_A and H_B are mutually coupled. (a) Situation pertaining to Booth’s rule (strong decrease of $^3J(\text{H,H})$ for an electronegative substituent S); (b) situation pertaining to Abraham’s rule [weak increase of $^3J(\text{H,H})$]; (c) situation where Abraham’s rule applies twice. This configuration occurs, for example, in cyclohexanes with H_A , H_B diequatorial and the S substituents diaxial

and Gatti¹⁰ with the aid of a series of 1,2-disubstituted ethanes $\text{CH}_2\text{X--CH}_2\text{Y}$. Their results are summarized in Figure 1.

For most practical purposes one needs to distinguish three different situations:

- (a) *Gauche* (*sc*) protons, J_g , with X in an *anti* orientation X_t : J_g decreases strongly with increasing electronegativity of X (Booth’s rule);
- (b) *Gauche* (*sc*) protons, J_g , and a substituent X in a *gauche* orientation with respect to its vicinal coupling proton, X_g : J_g increases with increasing electronegativity of X (Abraham’s rule);
- (c) *Anti* or *trans* (*ap*) protons, J_t , with X necessarily in a *gauche* position (not shown in Figure 1): J_t decreases with increasing electronegativity of X.

For X = oxygen in conformationally rigid pyranose sugars, a statistical analysis¹¹ of a large set of couplings indicated the following changes of 3J from X = H: situation (a) -1.8 Hz; (b) $+0.5$ Hz; (c) -1.45 Hz. This example clearly illustrates the fact that *gauche* (*sc*) couplings do not obey the simple cosinesquare rule. The various effects are additive to a good approximation, 24 additivity constants (eight different substituent types) gave an rms error of only 0.29 Hz for a test set consisting of 305 couplings.

Extended Hückel molecular orbital theory (EHT) calculations of $^3J(\text{H,H})$, carried out by Pachler^{12,13} on $\text{CH}_3\text{CH}_2\text{X}$ (X = H, CH_3 , NH_2 , OH, F), CH_3CHF_2 , and $\text{CH}_2\text{FCH}_2\text{F}$, indicated that an X substituent (or the C–X bond) induces an asymmetry in the Karplus curve. More refined EHT calculations^{14,15} confirmed this important finding and showed¹⁵ that mutual interaction between substituents cannot be neglected. Pachler^{12,13} described the calculated influence of the X substituent in terms of the summation of two effects: (1) an attenuation of the Fourier coefficients, i.e., as in equation (4) but with different k values for C_0 , C_1 , and C_2 ; (2) a phase shift, assumed to be proportional to the electronegativity of the substituent (Figure 2).

A phase shift can be formulated in several ways, for example by the introduction of sine terms.^{12,13} This leads to equation (5).

$$\begin{aligned}^3J(\text{H,H}) = C_0 + C_1 \cos(\phi) + C_2 \cos(2\phi) \\ + S_1 \sin(\phi) + S_2 \sin(2\phi)\end{aligned} \quad (5a)$$

with

$$C_m = C_{m0} + C_{m1} \sum_i \Delta\chi_i \quad \text{and} \quad S_m = S_{m1} \sum_i s_i \Delta\chi_i \quad (5b)$$

Figure 2 The calculated coupling constants (EHT method¹⁴) for ethane (solid line) and fluoroethane (dashed line) as a function of the HH torsion angle ϕ ; the positive direction of ϕ is defined according to IUPAC,¹⁷ the F atom occupies the S_1 substituent position shown in Figure 3 (sign factor $s_i = +1$). (Reproduced with permission from Elsevier Science Ltd., Kidlington, UK, from K. G. R. Pachler, *Tetrahedron*, 1971, **27**, 187)

In equation (5) the original Pachler equation^{12,13} is recast into a general Fourier expression.¹⁵ Moreover, the use of a separate and cumbersome proton-substituent torsion angle $\cdot\Phi_{HX}$ ^{12,13} is avoided by the introduction of the 'sign' factor s_i for each substituent S_i , s_i is +1 or -1 according to the definition by Haasnoot et al.¹⁶ (see Figure 3). (In this paper, as well as in others,¹⁵ the sign factor S_i was denoted ξ_i .)

It is important to keep in mind that the sign factors s_i of the substituents S_1 and S_2 (not to be confused with the Fourier coefficients S_1 and S_2) depend exclusively upon their stereochemical position with respect to their 'own' geminal coupling proton H_A . The following recipe applies: choose a Newman projection along the coupling path in such a manner that the chosen coupling proton H_A is located on the front side (Figure 3): S_1 is found at 120° and S_2 at -120° (positive angle defined as clockwise). Repeat the procedure with H_B up front, S_3 is at 120° and S_4 at -120° . The sign factors ($s_i = +1$ for substituents S_1 and S_3 , $s_i = -1$ for S_2 and S_4) are thus uniquely defined and are *independent* of the actual value of the torsion angle ϕ_{AB} . It goes without saying that in the case of a CH_2 group ($CH_{A1}H_{A2}$) one has to take care to select the proper H_A (interchange of H_{A1} and H_{A2} means a change of sign factor for the remaining substituent). Equation (6) simplifies the computer programming:

$$\sum_i s_i \Delta\chi_i = \Delta\chi_1 - \Delta\chi_2 + \Delta\chi_3 - \Delta\chi_4 \quad (6)$$

It is easily appreciated that the sine terms vanish in all cases where equivalent substituents (same $\Delta\chi_i$) occupy a +1 and a -1 position at the same time, for example in $-CH_2-CHX_2$ and the +, - coupling in the $-CHX-CH_2X$ molecular fragment. The above sign factor definition is associated with the definition of the positive direction of ϕ_{AB} according to IUPAC rules:¹⁷ positive when H_B rotates clockwise away from H_A , with the H_A, H_B eclipsed position taken as zero angle. Since the sine terms change sign at $\phi_{AB} = 0^\circ$ a change of substituent position from +1 to -1 can be depicted as a mirroring of the ΔJ curve (Figure 4). Equation (5) is invariant under electronegativity scale changes,¹⁵ aside from changes in the values of the coefficients C_m and S_m . It is a valid procedure to choose the relative electronegativity of hydrogen as zero and to fix $\Delta\chi$ of one other substituent. For practical reasons, a value $\lambda_{OR} = 1.40$ was selected, vide infra.

Figure 3 Definition of substituents with positive (S_1 and S_3) and negative (S_2 and S_4) sign factors s_i . Note that with each coupling nucleus in an sp^3-sp^3 fragment two geminal substituents with opposite sign factors are associated. The result of rotation of H_B with respect to H_A in the $-\phi$ direction is mathematically equivalent to the result of a $+\phi$ rotation with concomitant interchange of S_1 and S_2 . (Reproduced with permission of Elsevier Science Ltd., Kidlington, UK, from C. A. G. Haasnoot, F. A. A. M. de Leeuw, and C. Altona, *Tetrahedron*, 1980, **36**, 2783)

Haasnoot et al.¹⁶ also sought to describe the generalized Karplus equation by superimposing a phase shift upon the symmetrical ethane curve [equation (7) and Figure 4].

$${}^3J(H,H) = P_1 \cos^2(\phi) + P_2 \cos(\phi) + P_3 + \sum_i \Delta\chi_i [P_4 + P_5 \cos^2(s_i(\phi) + P_6 | \Delta\chi_i |)] \quad (7)$$

Comparison with equation (5) shows that C_{11} and S_{11} have been set to zero, and that in the $\cos(2\phi)$ and $\sin(2\phi)$ terms

Figure 4 The calculated difference curve $\Delta J = J(CH_3CH_2S) - J(CH_3CH_3)$ for a substituent S with a positive sign factor, showing the rationale behind the phase-shift parameters P_4 , P_5 , and P_6 in the Haasnoot equation (7)¹⁶

both a constraint (through a common parameter P_5) and a nonlinear $\Delta\chi_i$ dependence have been introduced. The invariance property (vide supra) does not hold for equation (7). The parameters P_1 – P_6 were empirically determined with the aid of a test set containing 315 couplings and corresponding ϕ_{HH} values.¹⁶ Each substituent was assigned a $\Delta\chi_i$ value according to Huggins,⁹ but empirically modified to account for the moderation of the electronegativity of the α substituent by attached atoms or groups (β substituents), other than hydrogen. A least-squares regression (J_{calc} versus J_{obs}) showed an rms error of 0.48 Hz and a correlation coefficient R of 0.992, in contrast to a similar regression using three parameters only, equation 1(a) (rms = 1.20 Hz, R = 0.947).¹⁶

2.3 Group Electronegativities and Nonadditivity Effects

Analysis¹⁵ of the results of a systematic series of calculations of $^3J(\text{H},\text{H})$ in a variety of mono-, di-, tri-, and tetrasubstituted ethanes by means of the EHT method (1404 J values) suggested that: (a) the use of standard relative electronegativities $\Delta\chi_i$ should perhaps be abandoned in favor of ‘best values’ of substituent constants λ_i derived from the data set at hand; (b) the nonadditivity effect (interaction between substituents) can be well described by the introduction of cross terms involving products $\Delta\chi_i\Delta\chi_j$ or $\lambda_i\lambda_j$. Díez et al.¹⁸ allowed the coefficients of equation (5b) to be quadratically dependent upon λ . It was shown that only certain combinations of cross terms can survive in such an expansion because of symmetry. Neglecting interactions between more than two substituents, one obtains equation (8), which is in fact an extension of equation (5).

$$C_m = C_{m0} + C_{m1}\sum_i\lambda_i + C_{m11}\sum_i\lambda_i^2 + C_{m12}(\lambda_1\lambda_2 + \lambda_3\lambda_4) + C_{m13}(\lambda_1\lambda_3 + \lambda_2\lambda_4) + C_{m14}(\lambda_1\lambda_4 + \lambda_2\lambda_3) \quad (8a)$$

$$S_m = S_{m1}\sum_i s_i\lambda_i + S_{m11}\sum_i s_i\lambda_i^2 + S_{m13}(\lambda_1\lambda_3 + \lambda_2\lambda_4) \quad (8b)$$

How can we determine the ‘substituent constants’ or ‘group electronegativities’ λ_i (which may contain other factors beside electronegativity)? Which of the cross terms in equation (8) are important and which can be neglected safely? In an attempt to answer these questions a combined empirical and theoretical approach was taken.

First, a large body of accurate (± 0.02 Hz) coupling data from mono- and 1,1-disubstituted ethanes was measured and analyzed.¹⁹ Because of torsional averaging, one isolates the ‘constant’ C_0 in equation (8a), $m = 0$. Excluding the self-quadratic term C_{011} from consideration,¹⁵ we obtain equation (9).

$$\langle^3J(\text{H},\text{H})\rangle = C_{00} + C_{01}(\lambda_1 + \lambda_2) + C_{012}(\lambda_1\lambda_2) \quad (9)$$

Not only were the coefficients C_{00} , C_{01} , and C_{012} optimized, but also the λ_i values. As explained above, parameter redundancies were removed by fixing the λ values of two different substituents present in the set: $\lambda_{\text{H}} = 0.00$ and $\lambda_{\text{OR}} = 1.40$ (measurements in solvent CDCl_3). The ‘best’ least-squares regression¹⁹ yielded equation (10):

$$\langle^3J(\text{H},\text{H})\rangle = 7.836 - 0.594(\lambda_1 + \lambda_2) - 0.423(\lambda_1 \cdot \lambda_2) \quad (10)$$

and in addition 50 λ_i values¹⁹ from 84 couplings; rms deviation = 0.018 Hz, maximum deviation = 0.06 Hz. A similar regression with the use of Huggins’s relative electronegativities yielded a 10-times larger rms deviation;¹⁹ however, this

Table 1 Substituent Parameters λ_i (Relative Group Electronegativities) Deduced from $\langle^3J\rangle$ of Various Mono- and 1,1-Disubstituted Ethanes in CDCl_3 and in D_2O , Equation (10). ^a λ_i range 0.60–0.62; for Z = halogen: Cl 0.85, Br 0.92, I 1.02.

^b λ_i range 0.65–0.78; for Z = halogen: F 0.65, Cl 0.82, Br 0.92, I 0.99.

regression also underlined the importance of the $\lambda_1\lambda_2$ cross term, at least for coupling to methyl protons.

Equation (10) proved to be highly useful for determining λ_i values of substituents not present in the original data set. Recently, special attention²⁰ was paid to solvent effects, in particular to the influence of the solvent D_2O in cases where the α substituent carries at least one nonconjugated lone pair of electrons that can readily act as a hydrogen bond acceptor. The vicinal coupling constants (and thus λ values) measured in common organic solvents (like acetone- d_6 , CD_3CN , and DMSO) hardly differ from those established in CDCl_3 . Table 1 presents a selection of λ_i values of substituents that are of particular value in the analysis of couplings measured in biomolecules.

Second, the least-squares analysis of the set of 1404 J values indicated¹⁵ that only two more cross terms (besides C_{012}) are probably important for use in equation (8a): C_{214} and either S_{211} or S_{213} .

Table 2 Final rms Deviations Obtained for $^3J(\text{H,H})$ with the Aid of the 299 J Test Set in the Various Approximations^a

Approximations	rms($\Delta\chi_i$) ^b (Hz)	rms(λ_i) ^c (Hz)	N^d
1. Karplus ^e	1.18	1.18	3
2. Karplus (linear) ^f	0.73	0.70	5
3. Pachler ^g	0.38	0.39	6
4. Haasnoot ^h	0.37	0.36	6
5. Díez–Donders ⁱ	0.38	0.33	6
6. Díez–Donders ^j	0.37	0.32	8
7. Díez–Donders ^k	0.36	0.31	7

^aThe C_{11} coefficient in equation (5b) was set to zero in all parameter optimizations. It is strongly correlated to some other coefficients.

^bWith the use of Huggins's relative electronegativity scale⁹ without β substituent correction.¹⁶

^cWith the use of experimental 'group electronegativity' values λ_i .^{19,20}

^dNumber of optimized parameters.

^eEquation (1a).

^fEquation (5), C coefficients only.

^gEquation (5), S_2 added (the rms error does not change when C_{11} and S_{11} are also added).

^hEquation (7), the coefficients (based on λ_i) are shown in equation (11).

ⁱEquation (8): C_{00} , C_{01} , C_{10} , C_{20} , C_{21} , S_{211} used, the coefficients (based on λ_i) are shown in equation (12).

^jEquation (8): C_{00} , C_{01} , C_{012} , C_{10} , C_{20} , C_{21} , C_{214} , S_{211} used.

^kEquation (8), as in footnote ^j, but C_{01} fixed on the 'ethane' value, and C_3 added ($C_3 = 0.1$ taken as the fixed value); the coefficients (based on λ_i) are shown in equation (13).

2.4 Parameter Optimizations

In order to test the ideas developed in the previous sections, an empirical approach was again taken. The original data set (315 J set)¹⁶ was first reduced to 299 J values (299 J set) by the deletion of norbornane- and norbornene-like structures [equations (5) and (7) do not contain correction terms for through-space effects,²¹ nor for deviations of CCH bond angles from the tetrahedral value, see Section 5]. Group electronegativities λ_i were selected for the various substituents present in the data set. The corresponding torsion angles were recalculated with the aid of the MM2-85 force field.²²

A series of least-squares parameter optimizations were carried out (see Table 2). It is of interest to watch the successive improvement, as judged by the drop in rms deviation, as we start (entry 1) from the original three-parameter Karplus equation [equation (1a)], and successively add (entry 2) an electronegativity dependence of the C_0 and C_2 coefficients, add (entry 3) the sine terms of the modified Pachler equation [equation (5)], use (entry 4) the Haasnoot approximation [equation (7)], and finally the Díez–Donders equation [equation (8)], the latter in three forms: (1) (entry 5), all cross terms zero, except the $S_{211} \sum_i S_i \lambda_i^2$; (2) (entry 6) as (1) but $C_{012} (\lambda_1 \lambda_2 + \lambda_3 \lambda_4)$ and $C_{214} (\lambda_1 \lambda_4 + \lambda_2 \lambda_3) \cos(2\phi)$ added; (3) (entry 7) as (2) plus a small threefold term $C_3 \cos(3\phi)$ added. In the latter parameter optimization, the C_{01} parameter was kept fixed on the value obtained from the 'ethane set' [equation (10)]; C_3 was fixed at -0.10 , a value close to that suggested by ab initio calculations.²³

The current parameters are shown in equations (11)–(13), with reference to the entries in Table 2.

Entry 4, Haasnoot:

$$^3J(\text{H,H}) = 14.64 \cos^2(\phi) - 0.78 \cos(\phi) + 0.58 \\ + \sum_i \lambda_i [0.34 - 2.31 \cos^2(s_i(\phi) + 18.40|\lambda_i|)] \quad (11)$$

Entry 5, Díez–Donders:

$$^3J(\text{H,H}) = (7.82 - 0.79 \sum_i \lambda_i) - 0.78 \cos(\phi) \\ + (6.54 - 0.64 \sum_i \lambda_i) \cos(2\phi) \\ + (0.70 \sum_i S_i \lambda_i^2) \sin(2\phi) \quad (12)$$

Entry 7, Díez–Donders:

$$^3J(\text{H,H}) = [7.41 - 0.59 \sum_i \lambda_i - 0.27 \sum_i (\lambda_1 \lambda_2 + \lambda_3 \lambda_4)] - 0.85 \cos(\phi) \\ + [6.84 - 0.87 \sum_i \lambda_i + 0.29 (\lambda_1 \lambda_4 + \lambda_2 \lambda_3)] \cos(2\phi) \\ - 0.10 \cos(3\phi) + (0.71 \sum_i S_i \lambda_i^2) \sin(2\phi) \quad (13)$$

The coefficients of equation (13) differ from previous ones²⁴ mainly because a constraint is now laid upon the $\cos(3\phi)$ coefficient, vide supra.

2.5 Summary of Results

1. In previous work the unsatisfactory rms deviation (0.48 Hz) obtained with the use of equation (7) and the full 315 J calibration set, prompted Haasnoot et al.¹⁶ to propose a division of the set into three parts. In other words, separate parameters were presented for ethane-like fragments which contained two, three, and four substituents, i.e. for $\text{CH}_2\text{--CH}_2$, CH--CH_2 , and CH--CH moieties, respectively. In contrast, all of the parameter optimizations reported in Table 2 were carried out on the full 299 J test set and it was found that a single optimization suffices to reach an acceptable rms deviation (0.37 Hz). Presumably, the improved agreement between J_{obs} and J_{calc} is at least, in part, the result of an improvement in calculated ϕ_{HH} values in the present calibration set.
2. The extended five-parameter Karplus equation [terms up to $\cos(2\phi)$ and linear electronegativity dependence of the Fourier coefficients C_0 and C_2] gives a 'best' rms deviation of only 0.70 Hz. Introduction of the asymmetry effect induced by a substituent diminishes the rms error in a dramatic way to less than 0.4 Hz. Systematic theoretical and experimental investigations into the effect of asymmetry on other types of vicinal couplings: $^3J(\text{C,H})$, $^3J(\text{N,H})$, $^3J(\text{P,H})$, $^3J(\text{P,C})$, unfortunately appear to be lacking, but see Section 3.2.
3. The Pachler Fourier series equation, equation (5), postulates a linear electronegativity dependence of the asymmetric part, expressed as $S_{21} \sum_i S_i \Delta\chi_i \sin(2\phi)$ or in the present work also as $S_{21} \sum_i S_i \lambda_i \sin(2\phi)$. The Haasnoot¹⁶ formulation, equation (7), implicitly contains $\Delta\chi_i^2 \cos(2\phi)$ and $\Delta\chi_i^2 \sin(2\phi)$ terms. The Díez–Donders equation, equation (8), explicitly uses an $S_{211} \sum_i S_i \lambda_i^2 \sin(2\phi)$ term. This term alone, in combination with the use of empirical group electronegativities λ_i , is responsible for a substantial decrease in the rms deviation compared with the linear Fourier: 0.33 Hz versus 0.39 Hz, compare entries 5 and 3 in Table 2.

- The introduction of two more cross terms (C_{012} and C_{214}) in the Díez–Donders formulation is only slightly effective, compare entries 5 and 6. This result comes as a surprise in view of the importance of the C_{012} term in the ethane/2-propane series [equation (10)].
- The use of a Pauling/Huggins-type electronegativity scale appears perfectly justified up to a certain level of approximation.

3 VICINAL COUPLING CONSTANTS INVOLVING HETEROATOMS

3.1 General Background

Measurement of heteronuclear coupling constants is an essential factor in the conformational analysis of biomolecules.^{25–28} Over the past three decades much effort has been invested into the delineation of Karplus-type relations for couplings involving one or more heteronuclei, either as coupling partner or contained in the coupling path. Unfortunately, there exists no firmly established quantitative correlation between $^3J(\text{H,C,C,H})$ and corresponding couplings to heteronuclei [$^3J(\text{X,C,C,H})$, $\text{X} = ^{13}\text{C}$, ^{15}N , ^{31}P], nor simple rules that predict the behavior of a vicinal coupling when a carbon atom in the coupling path is replaced by a heteroatom. In short, for each different combination of nuclei and coupling path, a Karplus-type equation must be parameterized from scratch, preferably on the basis of a large number of experimental couplings (calibration points). Semiempirical calculations of vicinal couplings cannot predict 3J with an accuracy desired by NMR spectroscopists, but such calculations, especially when carried out for a series of related molecular fragments,²⁵ may reveal details that would otherwise not be considered.

Thus far, the proposed parameterizations, resulting in a set of Karplus coefficients, rarely appear to have gone beyond the level of the three-parameter equation (1b). The problem of substituent effects on the A , B , and C coefficients is usually circumvented by the use of model compounds that contain the same (or at least similar) substituents as the compounds that one is interested in. The torsion angles necessary for such a parameterization are either estimated from molecular models, calculated by means of force-field methods, or taken from X-ray studies. Thus, one may hope to work effectively on the level of the five-parameter Karplus expression. It should be remembered that in the case of $^3J(\text{H,C,C,H})$ this level yields an rms deviation of 0.7 Hz (299 experimental calibration points); inclusion of an asymmetry term causes the rms deviation to drop to less than 0.4 Hz, vide supra.

A selection of coefficients for use in equation (1b) that are currently used in structural and conformational studies of proteins (Table 3) and nucleic acids (Table 4) is presented here. Some parameterizations have been carried out solely on the basis of semiempirical MO calculations in various approximations and these should perhaps be taken only as a rough guide. The coefficients for $^3J(\text{C,C,C,H})$ in Table 3 were determined from measurements³³ in norbornanes and are not necessarily representative for this coupling in open-chain compounds.

The most important asset that these coefficients presently offer is *not* their overall reliability (statistically tested in a small minority of cases) but the opportunities that are provided to remove ambiguities. For example, a single coupling constant $^3J(\text{H,H})$, measured along a given bond in an open-chain molecule, in the general case (single conformer assumed) corresponds to any one out of four torsion angles ϕ_{HH} . The situation is even more complex in the case of a conformational mixture. Modern NMR techniques allow us to measure accurately one or more $^3J(\text{X,H})$ and sometimes $^3J(\text{X,Y})$ along the same bond. The various Karplus curves are phase-shifted with respect to one another, because the X and/or Y nuclei are shifted by $\pm 120^\circ$ (sp^3) or 180° (sp^2). Thus, comparison of the various couplings often solves an assignment problem, always acute when dealing with diaster-eotopic nuclei, and/or may result in the selection of only one conformation that fits all the data.³⁸ Other applications are discussed in Section 4.

3.2 Vicinal Carbon–Proton Couplings $^3J(\text{C,C,C,H})$

This particular coupling constant appears to have resisted³⁹ all attempts to formulate satisfyingly simple and general trigonometric relationships similar to those developed for $^3J(\text{H,C,C,H})$. Although early MO calculations⁴⁰ on $^3J(\text{C,H})$ in substituted propanes already indicated that these couplings indeed obey a Karplus-type equation, in practice severe complications arose and progress remains slow. The present situation concerning $^3J(\text{C,H})$, Figure 5, can be summarized as follows:

- The ratio $^3J(\text{C,H})/^3J(\text{H,H})$ in molecular fragments where C replaces a corresponding H varies from 0.50 to 0.85 (mean 0.61 ± 0.065).²⁷ Thus, this ratio cannot be used with confidence to scale $^3J(\text{H,H})$ couplings or Karplus coefficients to fit $^3J(\text{C,H})$ data.
- The influence of electronegative substituents on rotationally averaged ($^3J(\text{C,H})$) in *t*-butyl derivatives correlates well with $^3J(\text{H,H})$, with the former slightly more sensitive to the electronegativity effect.⁴¹ More recently, an analysis of $^3J(\text{C,H})$ in carbohydrates⁴² suggested that oxygen (and carbon) substituents require a different set of coefficients [including the $\sin(2\phi)$ term] when moved from the β position to the γ position with respect to the coupling carbon nucleus, Figure 5. This implies that the minimum number of Karplus coefficients could be twice as large compared with the six that suffice to describe $^3J(\text{H,H})$.
- When the coupling ^{13}C nucleus itself carries one or more substituents besides hydrogen, matters are even more complicated. It has long been known that the nature of the X substituent has a profound influence on the magnitude of the rotationally averaged $^3J(\text{C,H})$ in $(\text{CH}_3)_3^{13}\text{CX}$ compounds.⁴³ Other factors besides electronegativity appear to be operative here. Moreover, MO calculations of $^3J(\text{C,H})$ in 1-fluoropropane⁴⁰ (Figure 5,

Figure 5 Torsion angles ϕ and ψ and atomic numbering for $^3J(\text{C,C,C,H})$. The coupling nuclei are marked with an asterisk

$X = F$) predicted that this coupling is substantially larger when ψ_{FC} is set at 180° than when it is set at 60° . In a recent MO study⁴⁴ on a series of 1-substituted propanes (Figure 5, $X = H, CH_3, NH_2, OH$, and F) both ϕ and ψ were varied from 0° to 360° in 30° steps. The rotation of ψ indeed appears to have a profound effect on $^3J(C,H)$. For example, for $\phi_{CH} = 180^\circ$ the calculated $^3J(C,H)(X = F)$ varies from 8.0 Hz ($\psi_{FC} = 0^\circ$) to 12.0 Hz ($\psi_{FC} = 150^\circ$). These predictions were experimentally verified by measurements on *cis*- and *trans*-4-*t*-butylcyclohexanols, where the effect is even larger than predicted for $X = OH$.⁴⁴ In the same paper⁴⁴ the set of 340 calculated $^{13}C-H$ couplings was fitted (rms = 0.27 Hz) with the aid of a nine-coefficient Karplus-type

expression. A 15-coefficient approximation was used to fit 39 experimental $^3J(C,H)$ values of cycloalkanols and pyranose sugars (rms = 0.30 Hz).⁴²

In summary, much work has to be done before $^3J(C,H)$ can be used to calculate torsion angles. In the meantime, it appears safe to apply the general rule: $^3J_{ap} \gg ^3J_{sc}$.

3.3 Vicinal Proton–Proton Couplings $^3J(H,N,C,H)$

This coupling, usually denoted $^3J_{HN\alpha}$, deserves some attention because it can be measured with precision in proteins and affords important information concerning the

Figure 6 Schematic representation of the main-chain torsion angles ϕ , ψ , and ω in polypeptides and proteins. The χ_1 angle is defined as the torsion angle $\text{N}-\text{C}^\alpha-\text{C}^\beta-\text{X}$; in many amino acids $\text{X} = \text{C}'$

Figure 7 Newman projection along the $\text{N}-\text{C}^\alpha$ bond of a peptide backbone showing three important vicinal coupling constants that supply information about the ϕ torsion angle

local backbone geometry along the ϕ angle (Figures 6 and 7). It should be noted here that in protein chemistry the torsion angle between coupling nuclei is denoted as θ ; for θ_{HNCH} one uses the relationship $\theta = \phi - 60^\circ$ (Figure 7).

Independent calibrations in terms of A , B , and C [equation (1b)], were carried out by Pardi et al.³⁰ (37 data points, rms = 0.87 Hz) and by Ludvigsen et al.²⁹ (112 data points, rms = 1.01 Hz), Table 3, on the basis of known X-ray structures. Inspection of the plots given suggests that corrections for differences in electronegativity of the various side chains might improve the rms deviation, especially for θ_{HNCH} near 180° and near 0° . The Karplus coefficients proposed by Bystrov²⁵ predict $J(180) = 10.9 \text{ Hz}$ and $J(0) = 8.7 \text{ Hz}$, the latter value is probably too large by about 1.5–2.0 Hz.

3.4 Vicinal ^1H and ^{13}C Couplings to ^{31}P in Phosphate Diesters

The vicinal couplings $^3J(\text{P},\text{O},\text{C},\text{H})$ and $^3J(\text{P},\text{O},\text{C},\text{C})$, taken in combination, yield important conformational information concerning two backbone torsion angles in nucleic acids: β (angle $\text{PO}_5'\text{C}5'\text{C}4'$) and ϵ (angle $\text{C}4'\text{C}3'\text{O}3'\text{P}$), (Figure 8). The Karplus coefficients that describe the angular dependence of $^3J(\text{P},\text{H})$ and $^3J(\text{P},\text{C})$ are relatively large. This fact contributed to the success of a different approach taken in the parameterization,⁴⁵ necessitated by the knowledge that phosphates (and sulfates) often display ‘nonclassical’ torsion angles, i.e. large deviations from ‘classical’ 180° and 60° angles. Moreover, it is desirable to avoid the use of crystallographic information which in individual cases can

Figure 8 Newman projections along the main-chain torsion angle ϵ and β in nucleic acids. The negative charge on the phosphate group is omitted. These angles are monitored by $^3J(\text{P},\text{O},\text{C},\text{H})$ and $^3J(\text{P},\text{O},\text{C},\text{C})$. (Reproduced by permission of Adenine Press from P. P. Lankhorst, C. A. G. Haasnoot, C. Erkelens, and C. Altona, *J. Biomol. Struct. Dyn.*, 1984, 1, 1387)

be biased by crystal-packing effects. Instead, the unknown backbone angle (ϵ) can be determined simultaneously with the Karplus coefficients, provided that several different couplings along the same central bond are available and that conformational purity along this bond can be attained. In the case discussed here, six Karplus coefficients and four torsion angles were determined from 17 experimental couplings in RNA compounds (rms = 0.2 Hz). As it turned out, the *mean* NMR value of ϵ_{ap} in the RNA molecules in the stacked form (219°) corresponded well with the *mean* of crystallographic determinations in similar RNAs (218°). The same Karplus coefficients (Table 4) are transferable to DNA molecules.⁴⁶

4 SELECTED APPLICATIONS OF 3J IN THE FIELD OF BIOMOLECULES

4.1 General Remarks

For more than a decade the conformational situation (‘structure’) of biopolymers, such as proteins and nucleic acids, was judged from characteristic NOEs. More recently, interatomic distances or NOEs were introduced as constraints in MD (molecular dynamics calculations) trajectories. However, without additional information, it is very difficult to judge whether or not conformational homogeneity exists along each chemical bond of interest. This is especially true in cases where a given conformer predominates; minor forms may then escape detection altogether. Contradictory NOEs certainly point to the simultaneous existence of various rotamers, but these are not easily quantified from NOE information. With the advent of more powerful NMR spectrometers and techniques, investigators are becoming more and more aware that homo- and heteronuclear coupling constants offer a rich source of the additional information that is required.

An important recent application^{48,49} of the Karplus coefficients involves the introduction of coupling constant restraints into molecular dynamics calculations. Defining $\Delta J = J_{\text{obs}} -$

J_{calc} , one adds a penalty function in the form of a pseudoenergy term $\frac{1}{2}k_i\Delta J_i^2$ to the force field for each conformational constraint along given torsion angles, in addition to the usual distance constraints obtained from NOEs. One of the advantages of this approach, when applied to multiple couplings along a chosen bond, is that conformational equilibria, which occur on a short timescale, can be handled with more confidence. Of course, the k_i 'force constants' should be weighed according to the reliability of J_{obs} and J_{calc} , but to date such information on J_{calc} is limited to a few types of vicinal couplings, see Sections 3.2–3.5. It was also proposed to incorporate time-averaged J values⁵⁰ as constraints; this idea was successfully tested on a cyclic peptide, antamanide ($^3J_{\text{HN}\alpha}$). Extension to multiple couplings about certain bonds undoubtedly will follow soon.

4.2 Amino Acids, Peptides, and Proteins

4.2.1 Main Chain Torsion Angles in Polypeptides and Proteins

The main chain in an amino acid sequence is characterized by three sequential torsion angles: ϕ , ψ , ω (Table 3 and Figure 6). For several reasons most attention was and still is focused on ϕ . This particular angle is correlated with the local shape of the sequence (α -helix, β -sheet, and various turns). In principle, ϕ can be monitored by the use of six different coupling constants (Table 3). Of these, $^3J(\text{H}, \text{N}, \text{C}^\alpha, \text{H}^\alpha)$ is the easiest one to measure, even in large proteins, followed by $^3J(\text{H}, \text{N}, \text{C}^\alpha, \text{C}^\beta)$.³⁸ Coupling to carbonyl carbon requires more effort and is difficult to obtain when the coupling is small. Nevertheless, a qualitative insight into the magnitude of two more ϕ couplings can be gained, at least in small cyclic peptides, from natural abundance NMR spectra; $^3J(\text{C}^\alpha, \text{C}^\beta, \text{N}, \text{H})$ and $^3J(\text{C}^\beta, \text{N}, \text{C}^\alpha, \text{H}^\alpha)$.^{38,51} Now that $^{13}\text{C}^{15}\text{N}$ isotopically-enriched proteins are becoming available, 3D and 4D NMR techniques offer new possibilities for measuring previously 'unmeasurable' couplings in large proteins, e.g., $^3J(\text{H}, \text{N}, \text{C}^\alpha, \text{C}^\beta)$.⁵² The ψ angle remains elusive. For $^3J(\text{H}^\alpha, \text{C}^\alpha, \text{C}^\beta, \text{N})$ and $^3J(\text{C}^\beta, \text{C}^\alpha, \text{C}^\beta, \text{N})$ very little reference material is available at present. A similar remark applies to $^3J(\text{C}^\alpha, \text{C}^\beta, \text{N}, \text{H})$, which coupling monitors the ω angle. In rigid domains, both ψ and ω can be determined from NOEs, however.

4.2.2 Side-Chain Conformations of Amino Acid Residues

The heteronuclear $^3J(\text{C}^\beta, \text{C}^\alpha, \text{C}^\beta, \text{H}^\beta)$ and $^3J(\text{N}, \text{C}^\alpha, \text{C}^\beta, \text{H}^\beta)$ couplings along with the two homonuclear $^3J(\text{H}^\alpha, \text{C}^\alpha, \text{C}^\beta, \text{H}^\beta)$ couplings allow the unambiguous diastereotopic assignment of the two β -methylene protons of the side chain of amino acid residues.^{51,53} Given the correct assignment of H^β (pro-*R*) and H^β (pro-*S*) (Figure 9), the conformational populations of the equilibrating three rotameric species can be calculated from the two $^3J(\text{H}^\alpha, \text{C}^\alpha, \text{C}^\beta, \text{H}^\beta)$ couplings when the limiting values ($^3J_{\text{ap}}$ and $^3J_{\text{sc}}$) are known. The Pachler⁵⁴ values $^3J_{\text{ap}} = 13.6\text{ Hz}$ and $^3J_{\text{sc}} = 2.6\text{ Hz}$ are still widely used in the literature, although Abraham et al.⁵⁵ in 1977 already pointed out that differentiation according to the electronegativity of the side chain as well as the inclusion of substituent orientation was called for. In that work⁵⁵ a simple additivity scheme of substituent constants for the prediction of $^3J_{\text{sc}}$ was proposed. For example, for $\text{X} = \text{carbon}$, the two $^3J_{\text{sc}}$ values predicted

Figure 9 Newman projections of the three staggered χ_1 side-chain conformations in an amino acid with two H- β protons. The three rotamers are designated I, II, and III for $\chi_1 = -60^\circ$, 180° , and 60° , respectively. For the sake of clarity pro-*R* and pro-*S* are abbreviated as *R* and *S*, respectively

were 3.4 Hz and 4.2 Hz, for $\text{X} = \text{oxygen}$, values of 2.2 Hz and 4.9 Hz were proposed. A more refined, but similar, approach is now possible through the use of equations (11), (12) or (13) in conjunction with the experimental group electronegativities λ_i . It appears best to distinguish three different groups of side chains A through C according to the respective λ_i values given in Table 1.

A: $\lambda_i = 0.42$ (Asn, Asp, His, Phe, Trp, Tyr)

B: $\lambda_i = 0.60$ – 0.75 (Arg, Cys, Gln, Glu, Leu, Lys, Met)

C: $\lambda_i = 1.25$ (Ser in D_2O), $\lambda_i = 1.33$ (Ser in CDCl_3)

The predicted $\text{H}^\alpha\text{H}^\beta$ limiting coupling constants for each of the three rotamers along χ_1 in peptides and proteins (idealized staggered geometry assumed), differentiated according to the electronegativity of the side chain, are shown in Table 5. The nature of the solvent plays a role only in the cases of free amino acids and N-terminal residues, because $\lambda(\text{NH}_2) > \lambda(\text{NH}_3^+)$ (Table 1).

Some examples of $\text{H}^\alpha\text{H}^\beta$ coupling constants and rotamer populations are displayed in Table 6. For purposes of comparison, the populations calculated with standard values⁵⁴ are also given. The differences between the new and the old population values are usually $\leq 7\%$, except for Ser ($\leq 10\%$). It is concluded that the trends recorded in the literature thus far remain valid. For future work requiring high precision, the new values are recommended. It is noted in passing that application of equations (11), (12), or (13) allows us to predict safely couplings pertaining to any deviation from ideal staggered geometries. A good example of nonstaggered situations occurs in proline residues. An analysis of the 10 coupling constants of proline and of 12 model compounds⁵⁹ with the aid of the Haasnoot equation [equation (7)]¹⁶ in conjunction with the pseudorotation model for five-membered rings⁶⁰ showed that the unsubstituted proline ring occurs in a practically 1:1 conformational equilibrium between N-type and S-type forms (see Section 4.3.1 for a discussion of N- and S-conformers). Recently, Karplus and co-workers⁶¹ successfully used the Haasnoot equation [equation (7)] to probe the motional characteristics of the four proline residues in the cyclic decapeptide antamanide on a picosecond time scale.

4.3 Nucleic Acids

The structural properties and current nomenclature rules¹⁷ of nucleic acid conformations have been treated by Wüthrich²⁸ and by Saenger.⁶² The conformational analysis of oligonucleotides with the aid of coupling constants has been reviewed by Altona,⁶³ backbone torsion angles are shown in Figures 8, 10, and 12.

Table 5 Predicted Limiting $H^\alpha H^\beta$ Coupling Constants (Hz) [Equation (13)] for Each of the Three Rotamers Along $C^\alpha C^\beta$ in Peptides and Proteins. Idealized Staggered Models Assumed. Three Classes of Amino Acid Residues A–C (See Text) are Differentiated According to the Group Electronegativity λ_i of the Side-Chain Substituent X, Figure 9. Because $\lambda(\text{NH}_2) > \lambda(\text{NH}_3^+) \approx \lambda[\text{NHC}(=\text{O})\text{R}]$ (Table 1) N-Terminal Residues are Further Differentiated According to Solvent Conditions

Cyclohexapeptide ⁵⁸ Phe ¹¹	DMSO	11.5	3.1	86(80)	2(5)	12(15)

^aThe rotamer populations are computed from three equations with three unknowns using standard matrix methods; for the sake of clarity pro-R and pro-S are abbreviated as R and S, respectively:

$$J_{\text{obs}(R)} = p_I J_{I(R)} + p_{II} J_{II(R)} + p_{III} J_{III(R)}$$

$$J_{\text{obs}(S)} = p_I J_{I(S)} + p_{II} J_{II(S)} + p_{III} J_{III(S)}$$

$$p_I + p_{II} + p_{III} = 1$$

The computation is simpler when it is assumed that all J_{sc} values are equal.⁵⁴

4.3.1 The Furanose Ring

The flexible five-membered sugar ring plays a pivotal role in nucleic acid structure and dynamic behavior. Structural differences between A-, B-, and Z-type duplexes are intimately correlated with specific conformational ranges of individual sugars. Within the B-DNA family each sugar responds to its

Figure 10 Conformational notation of the torsion angles of the backbone and χ of the base in nucleic acids¹⁷

surroundings (e.g., the base-stacking pattern) by an appropriate adaptation of its geometry. Careful analysis of sets of $^3J(\text{H,H})$ values reveals intimate details on the ‘atomic level’ that cannot be obtained from NOEs.^{64,65} Various reviews are available^{24,63–65} and only a brief outline of the coupling constant approach is sketched here.

Two distinct D-ribose conformations (better: conformational ranges) occur in nucleic acids, N-type (North, roughly C-3'-endo) and S-type (South, roughly C-2'-endo), Figure 11, which occur in fast equilibrium unless the stereochemical requirements of the helix impose restraints. For example, an RNA double helix consists of an N–N–N sequence of sugars, Z DNA of an S–N–S–N alternation. In B DNA the duplex structure allows the sugars some mobility to flip from S to N and vice versa. Pyrimidine sequences are relatively more mobile ($78 \pm 13\%$ S) than are purine sequences ($90 \pm 7\%$ S).²⁴ One always measures time-averaged couplings and shifts under ‘fast-exchange’ conditions. Nevertheless, it remains possible to extract quantitative information on geometry and conformational population from the couplings thanks to the fact that the five endocyclic torsion angles ν_i are mutually dependent via the two-parameter equation (14).

$$\nu_j = \phi_m \cos\{P + 0.8\pi(j - 2)\}, j = 0 - 4 \quad (14)$$

Figure 11 Schematic composite representation of the furanose conformations in nucleic acids: S-type (C-2'-endo/C-3'-exo) (left) and N-type (C-2'-exo/C-3'-endo) (right). (Reproduced by permission of Academic Press from J. van Wijk, B. D. Hückriede, J. H. Ippel, and C. Altona, *Methods Enzymol.*, 1992, **211**, 286)

in which ϕ_m represents the amplitude of pucker and P the phase angle of pseudorotation.⁶⁰ The torsion angles are numbered clockwise, starting with $\nu_0(\text{C}4'-\text{O}4'-\text{C}1'-\text{C}2')$. In D-sugars, N-type conformers are characterized by a positive sign of ν_3 , S-type forms by a negative sign of ν_3 . The (exocyclic) proton–proton torsion angles ϕ_{HH} are related to the ν_j -values via the pseudorotation parameters ϕ_m and P [equation (15)].⁶⁶

$$\phi_{\text{HH}} = a + b\phi_m \cos(P + \text{phase shift}) \quad (15)$$

where, in the idealized approximation, $b = 1$ and $a = 0^\circ$ for *cis* protons and $\pm 120^\circ$ for *trans* protons. Empirically established values for the parameters a and b in equation (15) for deoxyribose, ribose, arabinose, lyxose, and xylose are available.^{66,67} Equations (14) and (15) and the extended Karplus equation [equation (13)] are employed in the iterative least-squares program PSEUROT.⁶⁸ Given a complete set of experimental proton–proton couplings $J(1',2')$, $J(2',3')$, and $J(3',4')$ for riboses and, in addition, $J(1',2'')$ and $J(2'',3')$ for deoxyriboses, the program minimizes the functional $R = \sum (J_{\text{exp}} - J_{\text{calc}})^2$ and yields the pseudorotation parameters of the two stable furanose conformers and the mole fractions. The accuracy of the procedure is greatly enhanced when the conformational equilibrium displays a strong shift with temperature. Version 4.0 of the PSEUROT program is in the public domain (*Quantum Chemistry Program Exchange No. 463*, Indiana State University, 1983); this version employs equation (7) and the original coefficients.¹⁶ Later versions (PC, IBM compatible) 5.4 and 6.0 (see text) are available under licence from the author. Note that the PSEUROT programs are designed to yield the conformational characteristics of any saturated five-membered ring, provided that the appropriate vicinal $^1\text{H}-^1\text{H}$ couplings are input.

In NMR practice it is not always feasible to carry out the laborious spectral simulations that are required to obtain the individual coupling constants. Often, the sums of couplings to given protons are easily available, however, and these contain much the same information.^{24,69} In the case of DNA we define:

$$\Sigma 1' = J(1', 2') + J(1', 2'') \quad (16a)$$

$$\Sigma 2' = J(1', 2') + J(2', 3') + J(2', 2'') \quad (16b)$$

$$\Sigma 2'' = J(1', 2'') + J(2'', 3') + J(2'', 2') \quad (16c)$$

$$\Sigma 3' \{^3\text{P}\} = J(2', 3') + J(2'', 3') + J(3', 4) \quad (16d)$$

The $\Sigma 2'$ and $\Sigma 2''$ terms include the absolute value of $^2J(2', 2'')$ (approximately 14 Hz in deoxyribofuranose). A

graphical method, based on the theory employed in PSEUROT, successfully utilizes graphs of $\sum J$ versus P and $\sum J$ versus populations to solve the conformational problems.^{24,69} Recently, the graphical procedure was automated in program PSEUROT, Version 6.0.⁶⁸

4.3.2 Orientation of the Nucleic Acid Base

The glycosyl torsion angle χ (not shown) defines the orientation of the base with respect to the sugar ring.⁶² Two major orientations are known: *anti* and *syn*. In the more common *anti* form, the C-8-H-8 and C-6-H-6 vectors of the purine and the pyrimidine bases point roughly in the direction of the C-1'-O-4' bond and are antiparallel to the C-1'-H-1' bond. From pyrimidine model compounds the Karplus coefficients for $^3J(\text{C}-6, \text{N}-1, \text{C}-1', \text{H}-1')$ and $^3J(\text{C}-2, \text{N}-1, \text{C}-1', \text{H}-1')$ were determined⁴⁷ (Table 4) and from these values one predicts the following (very approximate) characteristics:

$$\text{antibase} : ^3J(\text{C}-6, \text{H}-1') \approx 9\text{Hz}, ^3J(\text{C}-2, \text{H}-1') \approx 3\text{Hz}$$

$$\text{synbase} : ^3J(\text{C}-6, \text{H}-1') \approx 4\text{Hz}, ^3J(\text{C}-2, \text{H}-1') \approx 7\text{Hz}$$

In a regular B-DNA structure with *anti* bases, the angle χ is well defined ($\pm 10^\circ$) from three NOE contacts: H-6/H-8-H-2', H-6/H-8-H-2'', H-6/H-8-H-3', but in exceptional cases where the base enjoys more conformational freedom measurement of $^3J(\text{C}, \text{H})$ may well supply valuable additional information.

4.3.3 Backbone Conformations of RNA and DNA

The six torsion angles along the nucleic acid backbone are denoted $\alpha-\zeta$, starting with P-O-5' as the central bond for α , Figure 10. NMR spectroscopy provides no direct grip upon the important phosphate diester torsions ζ and α ; these are usually determined from NOE-constrained MD trajectories. The remaining backbone angles β , γ , δ , and ϵ are monitored by various vicinal coupling constants. Because X-ray crystallography⁶² has made it clear that important deviations from pure staggered geometries (180° , 60°) in double-helical structures commonly occur, it is the task of the NMR spectroscopist to deduce at the same time values for the backbone angles as well as conformational populations. This is possible in principle because Nature has conveniently provided a sufficient number of coupling nuclei along the backbone that can be put into use.

It is often helpful to study the behavior of sums of couplings versus rotation about a given torsion angle. As an aid to the discussion, Table 7 has been prepared. The Karplus coefficients used to calculate the $^3J(\text{P}, \text{H})$ and $^3J(\text{P}, \text{C})$ values in Table 7 are taken from Table 4.

Torsion angle β (P-O5'-C5'-C4'), Figure 8. In 5'-mononucleotides of RNA and DNA, the $\beta^t(\text{ap})$ rotamer is invariably preferred ($>70\%$). In stacked oligonucleotides, the β^t angle is confined to a small range of values ($176 \pm 4^\circ$). Under the additional assumption that in unstacked ('melted') states an equilibrium exists between two or three rotamers (β^t , 175° ; β^+ , 60° ; β^- , 300°), a sum rule is easily derived [equation (17)]:

$$p(\beta^t) = (25.4 - \Sigma')/20.5 \quad (17)$$

where p stands for the fractional population and $\Sigma' = J(5', \text{P}) + J(5'', \text{P})$. Stereospecific assignments of H-5' and H-5'' are not

Table 7 Backbone Angles β , γ , and ϵ (°) of Nucleic Acids in the Most Populated Ranges and Corresponding Calculated Vicinal Coupling Constants (Hz) (See Text)

$J(\text{P,C} - 2')$	6.6	7.4	8.1	8.8	9.5
$J(\text{P,C} - 4')$	2.0	1.5	1.1	0.7	0.5

necessary at this stage. Unfortunately, we have no information concerning the true values of the β^+ and β^- angles, but it can be verified that nonclassical β_{sc} rotamers (e.g. β_{sc} , $\pm 90^\circ$) would introduce less than 2% error in the $p(\beta^t)$ value calculated from equation (17). The C-4',P coupling can be used as an independent check on the β^t population [equation (18)]:

$$p(\beta^t) = [^3J(\text{C-4}', \text{P}) - 0.7]/10.2 \quad (18)$$

Assuming that the H-5' and H-5'' resonances are assigned stereospecifically from NOEs, approximate values of the minor populations $p\beta^+$ and $p\beta^-$ are derived from $J(5',\text{P})$ and $J(5'',\text{P})$. Preference for β^+ was found to occur locally in a minihairpin loop.⁷⁰

Torsion angle γ (O5'-C5'-C4'-C3'), Figure 12. Nucleosides and mononucleotides in the solid state display a preference for γ^+ (76%), followed by γ^t (18%) and γ^- (6%). This rotamer distribution in the crystalline state is mirrored by the distribution found in aqueous solution at ambient temperatures. Crystallographic data reveal trends toward nonclassical angles: γ^+ , 53° ; γ^t , 180° ; γ^- , 290° . The right-handed helix requires a pure γ^+ rotamer; upon melting, conformational mobility is regained. The population γ^+ again follows from a sum rule

**Figure 12** Newman projections of the three γ rotamers in nucleosides. In nucleotides the OH group is replaced by an O- PO_3^- group

[equation (19)]:

$$p(\gamma^+) = (13.6 - \Sigma)/10.0 \quad (19)$$

where $\Sigma = J_{4'5'} + J_{4'5''}$. A pure or almost pure γ^t form is adopted by dG residues in Z DNA⁶² and at the 5'-3' loop stem junction in small hairpin loops in DNA, i.e. at the position of the local sharp turn of the backbone.⁷⁰ Such a turn is revealed by a large (>9 Hz) value of $^3J_{4'5'}$.

Torsion angle δ (C5'-C4'-C3'-O3'): This torsion angle is directly related to the pseudorotation parameters P and ϕ_m of

the D-(deoxy)ribose sugar by equation (20).⁶³

$$\delta = 120.6 + 1.1\phi_m \cos(P + 145.2) \quad (20)$$

Torsion angle ϵ (C4'-C3'-O3'-P), Figure 8. The study of the conformational behavior of this backbone angle is virtually impossible without the aid of vicinal ^{13}C - ^{13}P couplings because only a single $^3J(\text{P},\text{H})$ value is measured for each residue. The ϵ^+ rotamer is sterically 'forbidden'⁶³ and need not be considered. The two allowed conformational ranges, ϵ' and ϵ^- , are more or less symmetrically disposed with respect to H-3' and, without further information, $^3J(\text{P},\text{H})$ can give few clues concerning the ϵ'/ϵ^- rotamer population distribution. It is known, however, that $^3J(\text{P},\text{H}-3')$ of single-stranded RNA oligomers increases with increasing population of stacked (single-helical) conformer to a maximum of about 9 Hz, whereas $^3J(\text{P},\text{H}-3')$ in similar DNA compounds decreases to a minimum of about 4 Hz when fully stacked. This difference in behavior was quantitatively interpreted with the aid of ^{13}C NMR data.^{45,46,71} It turned out that there exists a strong correlation between the conformation of the sugar ring and the ϵ' angle. In RNA the stacked state strongly biases the sugar towards the N-type form [$\epsilon'_\text{N} = 219^\circ$; $^3J(\text{P},\text{C}-4') \approx 8$ Hz; $^3J(\text{P},\text{H}-3') \approx 9$ Hz], whereas in DNA the sugar mainly occupies the S-type range [$\epsilon'_\text{S} = 192^\circ$; $^3J(\text{P},\text{C}-4') \approx 10.7$ Hz; $^3J(\text{P},\text{H}-3') \approx 4.5$ Hz]. The ϵ^-_N combination appeared 'forbidden', whereas $\epsilon^-_\text{S} = 266^\circ$, corresponding with $^3J(\text{P},\text{C}-2') \approx 8.3$ Hz, remains allowed. The latter combination must be considered important, because X-ray crystallography has shown that it occurs in various residues throughout the double helix (BII form). We expect that the BII form will be studied in solution as soon as ^{13}C -enriched synthetic DNAs become available. Finally, it should be mentioned that ϵ'_N in DNA (212°) is smaller than ϵ'_N in RNA (219°).⁷¹

5 CAVEATS

The original optimism that arose among stereochemists when Karplus's first paper¹ on $^3J(\text{H},\text{H})$ in ethane appeared in 1959 soon gave way to grave scepticism in the course of the 1960s.² Nevertheless, the Karplus-type relationships are by now firmly rooted in stereochemical thinking. Perhaps unfortunately, not all the known ramifications are widely appreciated. Moreover, even in the situation of the best-known coupling, $^3J(\text{H},\text{C},\text{C},\text{H})$ along sp^3 - sp^3 C-C bonds, some influences that affect couplings have not been taken into consideration in the present contribution. At least three of these (perhaps not unrelated) influences are known, but as yet not understood to the extent that quantitative corrections to calculated couplings can be brought into play: (a) the β effect, the orientation of a β substituent appears to affect $^3J(\text{H},\text{C},\text{C},\text{H})$, an increase of about 0.5 Hz is noted for $^3J_{\text{ap}}$ when a C-O bond occurs in the *ap* position with respect to one of the coupling protons;¹¹ (b) the through-space (Barfield) transmission effect,^{72,73} first noted in norbornane-like structures but not necessarily limited to highly strained compounds; (c) bond angle deformations, semiempirical calculations^{2,74} predict that vicinal couplings depend significantly on the bond angles HCC' and CC'H' of the HCC'H' fragment. The effect would be maximal for $^3J_{\text{ap}}$ and $^3J_{\text{sp}}$. At this point a dilemma arises. Assuming that reliable

empirical corrections for influences (a)-(c) can be established, it would be necessary to introduce much detailed structural information concerning the molecular fragment under study into play before a measured coupling can be interpreted quantitatively in terms of the same structure. Undoubtedly, in the future this will be done for selected fragments which are of vital interest to researchers. However, we may also expect that for times to come present-day knowledge will suffice to solve stereochemical problems routinely along the lines pioneered by Karplus in 1959.¹

1 INTRODUCTION

In the last decade, NMR spectroscopy has become an important alternative to X-ray crystallography for the structural studies of molecules of biological interest. The principal advantage of NMR is that it allows the study of biomolecules in solution, thus closer to their real physiological environment. The method is limited, however, to biomolecules of relatively small size due to limitations in spectral resolution and line-broadening effects. The upper limit is presently situated around molecular weights of 30 kDa. Knowledge of three-dimensional (3D) structures might lead, for example, to a better understanding of structure–function relationships or recognition processes. For this purpose, accurate structures are required and, as we shall see, the use of so-called relaxation matrix approaches provides a means of improving the accuracy of the method.

The process of structure determination based on NMR data can be divided into four stages:

1. assignments of the proton resonances,
2. determination of structural constraints from NOE and J coupling data,
3. generation of structures,
4. refinement of these structures.

The first and laborious task of assigning proton resonances is still the main bottleneck of the structure determination, but progress is being made in this area by the development of new multidimensional NMR techniques [3D and four-dimensional (4D)]^{1–6} and the use of labeled samples (¹⁵N, ¹³C). Computational approaches are also being developed toward an automatic assignment of the NMR spectra (see *Analysis of Spectra: Automatic Methods*). We will not treat this aspect of the problem here, but concentrate on the last three stages involving the determination of structural constraints (distances, dihedral angles) and the generation and refinement of the structures.

Structure determination by NMR is based primarily on the nuclear Overhauser effect (NOE)⁷ (see *Nuclear Overhauser*

Effect). Its origin is dipolar cross relaxation between protons, which is a function of distances and molecular motions. Because of the approximate r^{-6} dependence of the NOEs on the interproton distances, these can only be measured between protons relatively close in space (< about 0.5 nm). NOEs are generally transformed into distance constraints which are then used, together with dihedral angle constraints obtained from J coupling data, for the generation of structures using Distance Geometry (DG)⁸ (see *Distance Geometry*) or Simulated Annealing (SA) techniques.^{9,10} These structures are then usually refined with a combination of restrained Energy Minimization and Molecular Dynamics (MD) simulations.¹¹ Genetic algorithms¹² and heuristic methods based on Kalman filter techniques¹³ can also be used for this purpose. Several approaches have been proposed for the interpretation of NOEs in terms of distances. The simplest one classifies the NOEs into strong, medium, and weak peaks and attributes corresponding distance ranges to these three categories. However, more accurate distances can be obtained from relaxation matrix calculations, which take into account all indirect magnetization transfers ('spin diffusion').^{14–23} A more direct method for refinement was proposed by Yip and Case,²⁴ in which NOE intensities are directly used as structural constraints, thus avoiding the transformation into distances. In this method, the structures are directly refined against experimental NMR data by comparison of theoretical and experimental NOE intensities.

In addition to NOEs and J couplings, chemical shifts can also provide structural information on biomolecules. Recent developments that permit the prediction of ¹H, ¹³C, ¹⁵N, and ¹⁹F chemical shifts should open new avenues to the structure refinement of proteins^{25–29} (see *Amino Acids, Peptides and Proteins: Chemical Shifts; Chemical Shifts in Biochemical Systems*).

In this review, we will first discuss the underlying theory of the NOE, including a description of intramolecular motions. The use of NOEs as structural constraints, indirectly by conversion into distances or directly by comparison of experimental and theoretical intensities, will be presented together with the most common methods used to generate and refine structures. This will be illustrated with results from our laboratory for the structure determination and refinement of the Arc repressor of phage P22, a dimeric DNA-binding protein (2 × 53 residues).

2 THE NUCLEAR OVERHAUSER EFFECT

2.1 Relaxation Matrix Theory

Multispin relaxation in a biomolecule in solution can be approximately described by the generalized Bloch equations. The evolution of the longitudinal magnetization components in a system of N spins is governed by a set of coupled differential equations of the form³⁰

$$\frac{d}{dt}\Delta\mathbf{M}(t) = -\mathbf{R}\Delta\mathbf{M}(t) \quad (1)$$

where the vector $\Delta\mathbf{M}(t)$ comprises the deviations from thermal equilibrium for all spins i

$$\Delta M(t)_i = [M_z(t) - M_0]_i \quad (2)$$

and $\mathbf{R}$ is the relaxation matrix. It comprises contributions from cross relaxation and from external relaxation. For a system of dipolar-coupled spins, neglecting cross correlation, $\mathbf{R}$ has the dimension of the number of spins N in the systems. Since the dipolar interaction is a function of time, the relaxation rates are intimately connected with the molecular motion. The elements of $\mathbf{R}$ can be expressed as^{7,30}

$$\begin{aligned} R_{ii} &= \rho_{ii} = K \sum_{j \neq i} [J_{ij}^0(0) + 3J_{ij}^1(\omega_0) + 6J_{ij}^2(2\omega_0)] + R_{\text{leak}} \\ R_{ij} &= \sigma_{ij} = K[-J_{ij}^0(0) + 6J_{ij}^2(2\omega_0)] \end{aligned} \quad (3)$$

where ω_0 is the Larmor frequency and $K = (2\pi/5)\gamma^4\hbar^2$; ρ_{ii} is the auto relaxation rate, with R_{leak} as an additional term to account for all nondipolar relaxation mechanisms, and σ_{ij} is the cross-relaxation rate between spins i and j . $J_{ij}^m(\omega)$ denotes the spectral densities at multiple values of the spin Larmor frequency $[(m \times \omega_0)]$ with $m = 0, 1, 2$. Cross relaxation is normally measured by observing intensity changes upon saturation or inversion of spins. Two-dimensional (2D) NMR techniques have been developed to investigate the resulting NOEs³¹ (see *Nuclear Overhauser Effect; NOESY*). The integrated intensities I_{ij} in a 2D NOE spectrum recorded with mixing time τ_m , are given by the matrix equation³¹

$$\mathbf{I}(\tau_m) = \exp(-\mathbf{R}\tau_m)\mathbf{M}(0) = \mathbf{A}\mathbf{M}(0) \quad (4)$$

which is the formal solution of the differential equation (1) where $\mathbf{M}(0)$ specifies the starting conditions. This defines the exponential matrix of normalized NOE intensities $\mathbf{A}$,

$$\mathbf{A} = \exp(-\mathbf{R}\tau_m) \quad (5)$$

that will be referred to as ‘the NOE matrix’.

The spectral densities $J_{ij}^m(\omega)$ in the definitions of the relaxation rates ρ_{ii} and σ_{ij} are cosine Fourier transforms

$$J_{ij}^m(\omega) = \int_0^\infty C_{ij}^m(t) \cos(\omega t) dt \quad (6)$$

where the $C(t)$ are correlation functions describing the time evolution of the dipolar interaction. Assuming that the molecule is a rigid body moving isotropically in solution, the correlation functions in equation (6) can be described by a simple exponential of the form $\exp(-t/\tau_c)$, τ_c being the correlation time for the overall rotation of the molecule. With this simple definition, the spectral density $J_{ij}^m(\omega)$ becomes

$$J_{ij}^m(\omega) = \frac{1}{4\pi r_{ij}^6} \left[\frac{\tau_c}{1 + (\omega\tau_c)^2} \right] \quad (7)$$

If the assumption of a rigid body is not valid, which is usually the case for biomolecules, the description of $C(t)$ by a simple exponential is no longer correct. The correlation function should then be defined in a more general form as

$$C_{ij}^m(t) = \left\langle \frac{Y_{2m}[\Phi_{ij}^{\text{lab}}(t_0 + t)] Y_{2m}^*[\Phi_{ij}^{\text{lab}}(t_0)]}{r_{ij}^3(t_0 + t) r_{ij}^3(t_0)} \right\rangle \quad (8)$$

Here the angular brackets indicate a time average over t_0 (which is equivalent to an ensemble average); Y_{2m} are the

second-order spherical harmonics and r and Φ^{lab} denote the length and polar angles of the interproton vector in the laboratory frame of coordinates. The form of the spectral density functions $J_{ij}^m(\omega)$ could be obtained experimentally from relaxation measurements. The feasibility of this approach has been recently demonstrated by Peng and Wagner^{32,33} who mapped the spectral densities of N–H vectors using heteronuclear relaxation experiments. In theory, this function can also be computed from a long MD trajectory. With present-day computational facilities $C(t)$ can only be computed with sufficient statistical accuracy for t values of the order of 0.1–1.0 ns. Fortunately, for many interproton vectors $C(t)$ is observed to reach a plateau value after a few ps, indicating that fast picosecond motions are well separated from slower processes.^{34,35}

Following the approach developed by Lipari and Szabo,^{36,37} a ‘model-free’ description of $C(t)$ can be set up in terms of two characteristic times, τ_p , the time in which $C(t)$ decays to the initial plateau value due to the fast internal motions, and τ_c , the correlation time for the overall rotation of the molecule. Assuming isotropic tumbling, and transforming to molecule fixed coordinates Φ^{mol} one has³⁴

$$C_{ij}^m(t) = \frac{\exp(-t/\tau_c)}{4\pi} C_{ij}^{\text{int}}(t) \quad (9)$$

where the internal motion correlation functions $C^{\text{int}}(t)$ are defined as

$$C_{ij}^{\text{int}}(t) = \frac{4\pi}{5} \sum_{n=-2}^2 \left\langle \frac{Y_{2n}[\Phi_{ij}^{\text{mol}}(t_0 + t)] Y_{2n}^*[\Phi_{ij}^{\text{mol}}(t_0)]}{r_{ij}^3(t_0 + t) r_{ij}^3(t_0)} \right\rangle \quad (10)$$

According to the addition theorem $C_{ij}^{\text{int}}(0) = \langle r_{ij}^{-6} \rangle$. The plateau value of the correlation function, $C_{ij}^{\text{int}}(t)$, can thus be defined quite generally as $S_{ij}^2 \langle r_{ij}^{-6} \rangle$, where S_{ij}^2 is a generalized order parameter. It has a value between 0 and 1, and can be calculated from an MD trajectory by using equation (10) and estimating the plateau value for each interproton vector. Within this simplified model the functions $C_{ij}^{\text{int}}(t)$ can be written as

$$C_{ij}^{\text{int}}(t) = \left\langle \frac{1}{r_{ij}^6} \right\rangle [S_{ij}^2 + (1 - S_{ij}^2) \exp(-t/\tau_p)] \quad (11)$$

where the initial decay has been written as an exponential. Combining equations (6) and (8)–(11), one arrives at^{34,35}

$$J_{ij}^m(\omega) = \frac{1}{4\pi} \left\langle \frac{1}{r_{ij}^6} \right\rangle \left[\frac{S_{ij}^2 \tau_c}{1 + (\omega\tau_c)^2} + \frac{(1 - S_{ij}^2) \tau_{\text{cp}}}{1 + (\omega\tau_{\text{cp}})^2} \right] \quad (12)$$

with $\tau_{\text{cp}}^{-1} = \tau_c^{-1} + \tau_p^{-1}$. Assuming that $\tau_p \ll \tau_c$, the second term in equation (12), related to the initial decay, vanishes and $J_{ij}^m(\omega)$ becomes

$$J_{ij}^m(\omega) = \frac{1}{4\pi} \left\langle \frac{1}{r_{ij}^6} \right\rangle \frac{S_{ij}^2 \tau_c}{1 + (\omega\tau_c)^2} \quad (13)$$

Besides the effects of fast local motions, other dynamic processes like, for example, methyl group rotation and aromatic ring flips can affect the relaxation behavior of

biomolecules. Their inclusion in the calculation of the theoretical NOE intensities has been described in detail by Koning et al.³⁸

2.2 Computational Aspects

Basically two methods are available for the computation of theoretical NOE intensities. These have been reviewed by Forster.³⁹ The first involves finding the eigenvectors and eigenvalues of the real symmetrical matrix $\mathbf{R}$ by standard matrix techniques.¹⁴

$$\Lambda = \mathbf{X}^{-1}\mathbf{R}\mathbf{X} \quad (14)$$

Combining this expression with equation (5) leads to

$$\mathbf{A} = \exp(-\mathbf{R}\tau_m) = \mathbf{X}\exp(-\Lambda\tau_m)\mathbf{X}^{-1} \quad (15)$$

The matrix diagonalization scales as N^3 , where N is the dimension of the matrix $\mathbf{R}$, and can become extremely time-consuming when N increases. The calculations can be speeded up by making use of the sparseness of the relaxation matrix; due to the r^{-6} dependence on the distances of the cross-relaxation rates, only a few elements of $\mathbf{R}$ are significantly larger than zero. Thus, it is possible to apply a spherical cutoff around each proton pair defining a subset of NOEs with only the neighbors. In this way, for each peak, a small eigenvalue problem can then be solved. The second approach⁴⁰ for the calculation of theoretical intensities is based on a numerical integration of the differential equations [equation (1)] describing the time dependence of the NOE intensities. Several integration schemes exist (Taylor series integration, Euler algorithm, various Runge–Kutta methods) and their accuracy and performance have been addressed by Forster.³⁹ A choice between the various methods has to be made depending on the dimension of the system and on the purpose of the NOE calculation; for example, numerical integration is no longer suitable if eigenvalues and/or eigenvectors are required (e.g. for the analytical NOE gradient; see Section 2.4).

2.3 From NOEs to Distances

2.3.1 Two-Spin Approximation

Proton–proton distance constraints are most conveniently derived from cross-peak intensities in 2D NOE spectra taken at various short mixing times. The initial buildup rate of these peaks is proportional to the cross-relaxation rates σ_{ij} between protons i and j .⁴¹ Therefore, these cross-relaxation rates can be measured either from a single 2D NOE spectrum taken with a sufficiently short mixing time or, more accurately, from a buildup series recorded with various mixing times.^{41–43} For a large molecule, assuming isotropical tumbling and no internal motions, the $J_{ij}^0(0)$ term in equation (3) dominates the cross-relaxation rate σ_{ij} which becomes simply related to the distance r_{ij} and the correlation time τ_c :

$$\sigma_{ij} \propto -\tau_c r_{ij}^{-6} \quad (16)$$

Therefore, with a known calibration distance r_{cal} , the proton–proton distances follow from the relationship

$$r_{ij} = r_{\text{cal}}(\sigma_{\text{cal}}/\sigma_{ij})^{1/6} \quad (17)$$

In practice equations (16) and (17) are only approximately valid. There are two main problems associated with accurate determination of proton–proton distances. The first is that proteins are not rigid bodies, and intramolecular mobility leads to nonlinear averaging of distances and to different effective correlation times for the different interproton vectors in the molecule. The second is that of indirect magnetization transfer or ‘spin diffusion’.⁴⁴ In reality the NOE cross peaks are the result of multispin relaxation and only in the limit of extremely short mixing times (where the signal-to-noise ratio is poor) is the two-spin approximation of equation (16) valid. For these reasons, a common approach is that of translating the NOE intensities into distance ranges (e.g. 0.2–0.3, 0.2–0.4, 0.2–0.5 nm for strong, medium, and weak NOEs, respectively) rather than attempting to obtain precise distances.⁴⁵

It has become possible to circumvent the spin diffusion problem by the use of relaxation matrix calculations, which take into account all indirect magnetization transfers. These methods will be developed in the next section.

2.3.2 Relaxation Matrix Approaches

When a model for the structure and dynamics of a molecule is available, the NOEs can be calculated from the spectral densities as shown above [see equations (3), (5), (14), and (15)]. The opposite route from experimental NOEs to relaxation parameters is also possible. The relaxation matrix $\mathbf{R}$ can be obtained after diagonalization of the NOE matrix $\mathbf{A}$.¹⁵

$$\mathbf{X}^{-1}\mathbf{A}\mathbf{X} = \mathbf{D} = \exp(-\Lambda\tau_m) \quad (18)$$

$$\mathbf{R} = -\mathbf{X}\left(\frac{\ln \mathbf{D}}{\tau_m}\right)\mathbf{X}^{-1} \quad (19)$$

Thus, theoretically the matrix $\mathbf{R}$ can be obtained directly from 2D NOE experiments taken at suitably chosen mixing times. In practice, this is not possible for large molecules, since the experimental NOE matrix is incompletely known due to overlap and missing assignments. Hybrid matrix methods have been proposed to circumvent this problem, in which the experimental data are supplemented by theoretical NOEs calculated from a model structure as implemented in IRMA,^{16,17} MARDIGRAS,¹⁸ MORASS,⁴⁶ FIRM,²² and CROSREL.²³ An overview of the Iterative Relaxation Matrix Approach (IRMA) is given in Figure 1.

The starting point for the calculations can be a single structure or an ensemble of structures, the relaxation matrix being built from the distances of the corresponding contributions averaged as $\langle r^{-6} \rangle$ in the latter case. A theoretical NOE matrix is then computed using standard matrix techniques [cf. equation (14) and equation (15)] and combined with the experimental data. The resulting matrix can then be transformed back to a corrected relaxation matrix from which new distances are calculated. These distances are used to generate an improved model. The whole process is repeated until convergence is obtained. In other implementations (MARDIGRAS, MORASS, FIRM), the theoretical information is progressively introduced in the hybrid matrix and the back-calculated corrected relaxation matrix is directly used to calculate new NOE

The derivative of A_{ij} with respect to the relaxation matrix element R_{kl} is defined as:

$$\frac{\partial A_{ij}}{\partial R_{kl}} = \lim_{h \rightarrow 0} \frac{A(\mathbf{R} + \mathbf{D})_{ij} - A(\mathbf{R})_{ij}}{h} \quad (24)$$

where $A(\mathbf{R} + \mathbf{D}) = \exp[-(\mathbf{R} + \mathbf{D})\tau_m]$ and $\mathbf{D}$ is a perturbation of $\mathbf{R}$ whose only nonvanishing component is h . By using standard quantum-mechanics perturbation expansion techniques one can identify the NOE matrix $\mathbf{A}$ as the evolution operator, the relaxation rate matrix $\mathbf{R}$ as the Hamiltonian, and τ_m as the imaginary time i . $A(\mathbf{R} + \mathbf{D})_{ij}$ can then be approximated to first-order in h as

$$A(\mathbf{R} + \mathbf{D})_{ij} = A(\mathbf{R})_{ij} - h \int_0^{\tau_m} \exp[-\mathbf{R}(\tau_m - s)]_{ik} \exp(-\mathbf{R}s)_{lj} ds \quad (25)$$

Substituting this expression in equation (23) gives the derivative of the NOE with respect to R_{kl} :

$$\frac{\partial A_{ij}}{\partial R_{kl}} = - \int_0^{\tau_m} \exp[-\mathbf{R}(\tau_m - s)]_{ik} \exp(-\mathbf{R}s)_{lj} ds \quad (26)$$

The integral in equation (26) can be computed efficiently with numerical integration techniques. In addition, since no eigenvectors of $\mathbf{R}$ are required as for the expression in equation (21) any technique that allows a fast and accurate evaluation of the NOE intensities can be used in place of the diagonalization method. The derivative in equation (26) has been shown to be equivalent to the analytical expression proposed by Yip and Case²⁴ [equation (21)] and, from preliminary results, appears to be significantly faster than the expression in equation (21).⁶¹

2.4.2 3D NOE–NOE Intensities

For larger molecules considerable overlap can exist in 2D spectra. This overlap can be overcome by spreading the peaks in a third dimension and new multidimensional NMR techniques were therefore developed.^{1–6} A similar procedure as with the refinement of NOE data from one-dimensional and 2D spectra can be followed for the treatment of NOE intensities from 3D spectra.

The intensities of cross peaks in a 3D spectrum are proportional to the transfer efficiencies of the two mixing periods of the experiment. The net transfer can be described in general as:

$$T_{ijk}^{3D} = T_{ij}(1)T_{jk}(2) \quad (27)$$

where $T_{ij}(1)$ and $T_{jk}(2)$ describe the magnetization transfer efficiencies for each separate mixing period and correspond to NOE transfer, exchange, or J transfer. The use of cross-peak intensities in a structure refinement procedure requires calculation of the gradients of these 3D intensities with respect to the coordinates of the protons in a molecule. The gradient of a 3D peak can be written as the sum of two terms containing the separate gradients of $T_{ij}(1)$ and $T_{jk}(2)$:

$$\nabla T_{ijk}^{3D} = T_{jk}(2)\nabla T_{ij}(1) + T_{ij}(1)\nabla T_{jk}(2) \quad (28)$$

These equations can be generalized for even higher dimensional experiments. Thus, given a valid model for the calculation of the magnetization transfer efficiencies and their derivatives, 3D peaks can be used as constraints in a direct refinement procedure.

In particular, 3D NOE–NOE spectra appear to be suitable for this purpose. This latter technique was developed for the direct observation of indirect NOE magnetization transfer ('spin diffusion') as occurs in larger biomolecules.⁶² Kessler et al.⁶³ and Habazettl et al.⁶⁴ described the quantitative use of 3D NOE–NOE cross peaks for obtaining distance constraints, which are used by DG or restrained MD computations. It is also possible to use the intensities of such 3D spectra as direct constraints for structure refinement.⁶⁵ In a 3D NOE–NOE spectrum the 3D cross-peak intensities A_{ijk}^{3D} can be calculated from their separate 2D NOE transfer efficiencies. The computation of the 3D NOE–NOE intensity A_{ijk}^{3D} then amounts to the multiplication of the calculated 2D contributions A_{ij} and A_{jk} . A similar NOE restraining potential function can be defined as for the direct refinement with 2D NOE data.⁶⁵ The same approximations as for 2D data can be used for the computation of the 3D NOE–NOE forces.

The feasibility of direct NOE refinement with 3D NOE–NOE data was demonstrated by Bonvin et al.⁶⁵ for a small peptide with synthetic 3D data using a simple approximation for the derivative of the NOE intensity based on the first two terms of the expansion of the exponential function [equation (23)].⁶⁵ A similar approach has been developed since by Habazettl et al.⁶⁶ and applied to the structure refinement of a few proteins [*Cucurbita maxima* trypsin inhibitor I (CMTI-I), hisactophilin, mucous protease inhibitor (MPI)].^{66,67} The main problem with the application of the method lies in the assignment of cross peaks of a 3D NOE–NOE spectrum. The huge amount of data contained in a 3D experiment requires an efficient program for automatic assignment and peak-picking before a refinement based on 3D NOE–NOE intensities can be undertaken.

3 STRUCTURE CALCULATIONS

3.1 Distance Geometry (DG)

The metric matrix DG algorithm^{68,69} was known well before structure determination by NMR became possible.^{70,71} This method does not rely on a starting conformation, is free from operator bias in this respect, and is therefore very attractive for structure determination. The DG procedure amounts to the following. First, upper and lower bound matrices $\mathbf{U}$ and $\mathbf{L}$ are set up for all atom–atom distances of the molecule. Some of the elements u_{ij} and l_{ij} follow from standard bond lengths and bond angles of the covalent structure and from experimentally found distance ranges from NOEs and J coupling constants. A bound smoothing procedure using triangle inequalities extends the constraints to all elements of $\mathbf{U}$ and $\mathbf{L}$. This procedure can even be extended to satisfy tetrahedron inequalities as for example implemented in the DG-II package⁸ (see **Distance Geometry**). Then, a distance matrix $\mathbf{D}$ is set up with distances chosen randomly between upper and lower bounds, $l_{ij} \leq d_{ij} \leq u_{ij}$. The elements of $\mathbf{D}$ can be chosen in such a way that they not only lie between their respective upper and lower

bounds, but also themselves obey the triangle inequalities; this latter technique is known as *random metrization*. The so-called ‘embedding’ algorithm then finds the best 3D structure consistent with the distances d_{ij} . This structure must be optimized with an error function consisting of chirality and distance constraints. This forces the amino acid side chains to adopt the correct chirality and the distances to satisfy the upper and lower bound criteria, although usually the DG structures still contain a number of violations of the distance bounds. By repetition of the DG calculations with randomly chosen distance matrices $\mathbf{D}$, families of structures can be obtained that allow one to judge how uniquely the structure is determined by the constraints.

Another method, also termed distance geometry, but using a quite different mathematical procedure, was suggested by Braun and Gö. ⁷² Here, the biomolecular conformation is calculated by minimizing a distance constraint error function. Special features of the method are that dihedral angles are used as independent variables rather than Cartesian coordinates and that it uses a variable target function, first satisfying local constraints (between amino acids nearby in the polypeptide chain) and later including long-range constraints. This approach avoids becoming trapped in a local minimum of the target function. Usually one starts with various initial conformations obtained by taking random values for the dihedral angles. This method, which has been implemented since in various programs, e.g. DISMAN ⁷² and more recently DIANA, ⁷³ has rather similar efficiency and convergence properties as the metric matrix distance-geometry algorithm.

3.2 Simulated Annealing (SA)

Although the DG methods do not need starting structures and are therefore not subject to operator bias, this does not mean that they sample the allowed conformational space (consistent with the bounds) in a truly random fashion. Simplified MD calculations with only geometric constraints were developed to increase the sampling of the DG methods. These are termed, in general, simulated annealing (SA) procedures. Although these can be directly used to generate structures starting from random coordinates, they are most commonly combined with DG calculations, the starting structures for the SA stage being obtained by DG embedding. Simulated annealing involves raising the temperature of the system followed by slow cooling in order to overcome local minima and locate the region of the global minimum of the target function V_{tot} (cf. Nilges et al.) ⁹. This is achieved by solving Newton’s equations of motion

$$m_i \ddot{\mathbf{r}}_i = \mathbf{F}_i \quad (29)$$

with the forces given by

$$\mathbf{F}_i = -\partial V_{\text{tot}} / \partial \mathbf{r}_i \quad (30)$$

The potential V_{tot} usually contains the following terms:

$$V_{\text{tot}} = V_{\text{covalent}} + V_{\text{repel}} + V_{\text{disre}} + V_{\text{dihre}} + V_{\text{NOE}} \quad (31)$$

V_{covalent} is a potential to maintain correct bond lengths, angles, planes and chirality, V_{repel} is a simple repulsion term to prevent unduly close nonbonded contact, V_{disre} and V_{dihre} represent

the experimental NOE distance and dihedral angle constraints, respectively, and V_{NOE} is an extra term for direct comparison of theoretical and experimental NOE intensities as defined in equation (20). Usually the NOE distance constraints are represented by a flat well potential of the form

$$V_{\text{disre}} = \begin{cases} \frac{1}{2} K_{\text{disre}} (d_{ij} - l_{ij})^2 & 0 \leq d_{ij} \leq l_{ij} \\ 0 & l_{ij} \leq d_{ij} \leq u_{ij} \\ \frac{1}{2} K_{\text{disre}} (d_{ij} - u_{ij})^2 & u_{ij} \leq d_{ij} \end{cases} \quad (32)$$

where l_{ij} and u_{ij} are the value of lower and upper limits of the target distances, respectively. Other forms that contains a linear part at long distances are also used ⁷⁴ to avoid too large energies, which may give computational problems. A similar definition as in equation (32) can be used for dihedral angle constraints, but other forms have also been proposed such as: ⁷⁵

$$V_{\text{dihre}} = K_{\text{dihre}} [1 - \cos(\phi - \phi_0)] \quad (33)$$

where ϕ_0 represents the dihedral angle value obtained from J coupling data. The various terms in equation (31) have variable force constants, which can be progressively increased during the annealing.

The combination of DG, for generating starting structures with an approximate folding by embedding a subset of atoms, and SA calculations, provides a powerful and efficient tool for the structure determination of biomolecules. ^{9,76} This hybrid method should be particularly useful for solving the structure of large proteins for which computational costs may become a limiting factor.

3.3 Restrained Molecular Dynamics and Energy Minimization (RMD, REM)

The quality of biomolecular structures based on geometric constraints can be improved by taking energy considerations into account. For instance, in DG structures amino acid side chains often adopt eclipsed conformations. Also, hydrogen bonds and salt bridges may not be formed unless they are specifically introduced as constraints. In RMD refinement structures are optimized simultaneously with respect to a potential energy function and a set of experimental restraints. Of course the success of this method now depends to a large extent on the quality of the force field used. It is therefore important to realize the limitations and approximate nature of this force field, especially when the calculations do not include solvent molecules.

In RMD calculations, equation (29) and equation (30) are integrated with the potential function given by

$$V_{\text{tot}} = V_{\text{bond}} + V_{\text{angle}} + V_{\text{torsion}} + V_{\text{vdW}} + V_{\text{Coulomb}} + V_{\text{disre}} + V_{\text{dihre}} + V_{\text{NOE}} \quad (34)$$

The first two terms tend to keep bond lengths and angles at their equilibrium values. V_{torsion} is a sinusoidal potential describing rotations about bonds; for V_{vdW} (the van der Waals interaction) usually a Lennard–Jones potential is taken, and V_{Coulomb} describes the electrostatic interactions. The three last

terms, similar to those in equation (31), distinguish RMD from more conventional MD simulations.

An RMD simulation is usually preceded and followed by REM using steepest descent or conjugated gradient methods to bring the energy down to an acceptable level. Using the same potential energy function as RMD [equation (34)] REM usually induces only small changes in the structures by driving them to the closest minimum and is not able to take them out of this. By contrast, RMD is able to overcome barriers of the order of kT because of the kinetic energy in the system and therefore has a much larger radius of convergence. The RMD method works as an efficient minimizer, since excess potential energy, converted to kinetic energy, is drained off by coupling the system to a thermal bath of constant temperature. Sampling of the conformational space consistent with the experimental constraints can be increased by using high-temperature simulations⁷⁷ or potential energy annealing conformational search methods (PEACS)⁷⁸ in which the potential energy is coupled to a reference energy bath whose energy level is progressively decreased over the run, or by introducing a fourth dimension⁷⁹ as recently implemented in GROMOS (4D MD),⁸⁰ which, by increasing the number of degrees of freedom in the system, allows one to circumvent energy barriers present in the 3D potential energy hypersurface.

Further extensions of the method, especially useful for highly mobile structures, include time-averaging⁵⁴ or ensemble-averaging⁵⁵ of the experimental restraints. In these methods, V_{disre} is calculated from time- or ensemble-averaged distances instead of instantaneous ones. Forces are thus applied on the corresponding protons only if the *averaged* distance violates the restraint. These methods allow a larger conformational freedom consistent with the NOE restraints. The use of time-averaged restraints has recently been described for direct structure refinement with J coupling⁵⁶ and NOE⁵⁷ data.

4 QUALITY OF THE STRUCTURES

Important factors for assessing the quality of the NMR structures usually obtained with a combination of the above described methods are the number and distribution of the NOE and dihedral angle constraints and the number of stereospecific assignments. Several other criteria have also to be considered, but these will all depend, to some extent, on the factors mentioned above. The precision of the structure is generally given by the average root mean squared deviations (rmsd) (pairwise or from the average coordinates). These are usually calculated for the backbone and all atoms, respectively, and sometimes on a substructure. The rmsd as a function of the residue sequence can also be useful for identifying less well-defined regions in a structure. Another useful parameter to assess the precision of solution structures is the angular order parameter proposed by Hyberts et al.⁸¹

$$S_{\phi}^{\text{angle}} = \frac{1}{N_{\text{struc}}} \left[\left(\sum \cos \phi \right)^2 + \left(\sum \sin \phi \right)^2 \right]^{1/2} \quad (35)$$

It has the advantage that, contrary to rmsd, it does not require the superimposition of the structures. Angular order parameters (S^{angle}) are generally given as a function of

the residue sequence for backbone ϕ , ψ and side-chain χ_1 dihedral angles. S^{angle} values of 0.9 and 0.8, for example, indicate very well-defined dihedral angles with fluctuations of $\pm 24^\circ$ and $\pm 40^\circ$, respectively. We have to keep in mind, however, that the rmsd etc and angular order parameters give an indication of the precision of the structure, but are not a direct indication of its accuracy. Structures with very low rmsd can still be wrong! To judge the quality, we have to take several other criteria into account: the stereochemical quality (e.g. via ϕ , ψ Ramachandran plots), the deviations from the idealized covalent geometry, the conformational energy, residual restraints violations, the presence of hydrogen bonds, and a good packing of the structures; these are criteria commonly used for this purpose. Studies of the stereochemical quality of crystal and NMR protein structures have resulted in useful criteria to assess the quality of these structures.^{82,83} These criteria, among which are the percentage of residues in the favorable area of the Ramachandran plot and the χ_1 dihedral angles- and hydrogen-bond energy standard deviations, can be easily checked with the program PROCHECK,⁸² which allows a fast and simple evaluation of the stereochemical quality of a protein structure. Another criterion to assess the quality of the structures obtained from NMR data is directly to compare calculated and experimental NOEs. The fit can be described by a residual index or R factor in a similar manner as in X-ray crystallography. Several R factor definitions have been proposed^{47,84,85} and can all be represented by a general equation of the form:

$$R = \frac{\sum_i w_i |N_i^{\text{theo}} - N_i^{\text{exp}}|}{\sum_i w_i |N_i^{\text{ref}}|} \quad (36)$$

where $N_i = A_i$ or $N_i = (A_i)^{1/6}$ with, in the denominator, N_i^{ref} defined as $N_i^{\text{ref}} = N_i^{\text{exp}}$ or $N_i^{\text{ref}} = \frac{1}{2} (N_i^{\text{exp}} + N_i^{\text{theo}})$, w_i are weighting factors that can be chosen equal to the mixing times, since NOEs measured at longer mixing times are expected to have a better signal-to-noise ratio. The simplest one, with $N_i = A_i$ and $N_i^{\text{ref}} = N_i^{\text{exp}}$, is similar to the X-ray definition.⁸⁴ For NMR, however, other functions may be more appropriate since we are dealing principally with two problems. First, the range of NOE intensities is quite extended (by more than a factor of 1000) and R might be dominated by strong peaks, corresponding to short distances in the structures which are expected to be less important for determining the 3D structure. A sixth-root residual index, $R^{1/6}$, where $N_i = (A_i)^{1/6}$, allows for a more even contribution of weak and strong NOEs in the R factor.^{47,84} The second problem inherent to the R factor comes from the approximate r^{-6} dependence of the NOEs. Because of this extreme distance dependence, the R factor function is asymmetric, the error increasing strongly when the distances are shorter than the target distances. Normalizing the errors by the sum of both experimental and theoretical NOE intensities, $N_i^{\text{ref}} = \frac{1}{2} (N_i^{\text{exp}} + N_i^{\text{theo}})$, should avoid this problem.⁸⁵ To give a better picture of the quality of the structures, a distinction can be made between intra- and interresidue peaks and the R factors can be calculated as a function of the residue sequence, which allows one to recognize problem regions in the structures.

5 APPLICATION: THE ARC REPRESSOR

The structure refinement process using relaxation matrix calculations can be best illustrated using a specific example: the Arc repressor. The solution structure of the Arc repressor of *Salmonella* bacteriophage P22, a dimeric sequence-specific DNA-binding protein,⁸⁶ has been determined from 2D NMR data using an ‘ensemble’ IRMA followed by direct NOE refinement with DINOSAUR.⁸⁷

An 824 NOE buildup series in H₂O and D₂O and 130 additional qualitative distance constraints were collected for Arc. This resulted in a set of 954 constraints consisting of 350 intraresidue, 215 sequential, 181 medium range, and 208 long-range constraints; 144 of the total set correspond to intermonomer constraints. Twenty-four hydrogen bonds were also explicitly defined. The constraints were duplicated to account for the dimeric nature of Arc giving a total set of 2004 constraints (NOEs + hydrogen bonds). Of the set of 954 constraints per monomer, 824 NOEs with good quality buildup curves were used in the IRMA and DINOSAUR calculations, the others being introduced as qualitative constraints. From the stereospecific assignment procedure, which resulted in the assignment of 16 β -methylene diastereotopic proton pairs (40%) and of the methyl groups of four valine residues, constraints could be imposed on 21 χ_1 dihedral angles.

In the initial stage, a set of 51 structures was generated with DG and further refined with a combination of REM and RMD using the GROMOS force field⁸⁸ in a parallel refinement protocol. Distance constraints were obtained from the set of 854 NOE buildups via relaxation matrix calculations from the ensemble of structures, except for the initial cycle in which a structure obtained by Breg et al.⁸⁹ was chosen as the model. Methyl group rotation, aromatic ring flips, and internal mobility effects (via order parameters obtained from a free MD run in water) were included in these calculations. Convergence was obtained after three IRMA cycles. The best 16 structures were finally refined with direct NOE constraints following a slow-cooling SA protocol from 600 to 1 K in 1.5 ps followed by REM.⁸⁸ In this final refinement stage, theoretical NOE intensities were directly compared with the experimental data using a simple quadratic restraining potential [$x = 1$, $y = 2$ in equation (20)] with, as weighting factor, an experimental error defined as $w_{ij} = (N + \epsilon A_{ij}^{\text{exp}})^{-2}$.⁵⁰ N corresponds to a noise level and ϵ to a relative error on the experimental intensities. The forces were derived using the simple two-spin approximation for the gradient of the NOE function [equation (23)]. Dynamic assignment was applied to the peaks involving unassigned diastereotopic groups.

A view of the backbone of the 16 best Arc structures at various stages during the refinement (DG/SA, IRMA 1st, 2nd, and 3rd cycles, and DINOSAUR) is presented in Figure 2, which clearly shows the improvement of the structures. The precision of the well-defined region of Arc (residues 8–48) including the β -sheet and the two α -helices increases during the IRMA refinement as confirmed by the rmsd (from the average) shown in Figure 3(a). The rmsd for the backbone atoms decreases from 1.0 Å for the DG/SA structures to 0.50 Å for the structures obtained after the third IRMA cycle. This value increases slightly to 0.55 Å after the direct NOE refinement indicating that the use of direct NOE constraints might introduce more variability in the structures (due to spin diffusion effects there are more ways to fulfill a

Figure 2 View of the Arc repressor structures during the refinement with NMR constraints. The structures corresponding to the 16 best final conformations are shown directly after the DG/SA calculations in the first IRMA cycle, after each IRMA cycle, and after direct NOE refinement with DINOSAUR. The structures were superimposed on C- α , C, N atoms of the well-defined region of Arc (residues 8–48 of each monomer)

Figure 3 (a) All heavy atom and backbone atom rmsd from the average for the well-defined region of the Arc repressor (residues 8–48 of each monomer) calculated for an ensemble of 16 structures as a function of the refinement. The structures were superimposed on backbone atoms of the well-defined core. (b) R factors ($Q^{1/6}$ definition) of the Arc structures as a function of the refinement

NOE constraint than a distance constraint). The R factors ($Q^{1/6}$ definition),⁸⁷ however, show a substantial decrease during the DINOSAUR refinement step as can be seen from Figure 3(b). The final structures satisfy the NMR constraints with no significant deviations from dihedral angle restraints obtained from J coupling data and very low R factors, indicating a very good agreement with the experimental NOE data.

The distribution of the experimental constraints as a function of the residue sequence is plotted in Figure 4, together with the precision (rmsd on C- α and all heavy atoms), the backbone angular order parameters [equation (35)] and the $Q^{1/6}$ factors. A correlation can be noticed between the number of constraints and the precision per residue, but no such relationship can be found for the $Q^{1/6}$ factors which all represent low values (~ 0.05) (for comparison, the $Q^{1/6}$ factors for a linear chain of Arc have values of around 0.55). Regions of high variability are found in the N- and C-terminal parts for which few

Figure 4 Number of constraints, rmsd (from the average) on C- α atoms and on all heavy atoms [the structures were superimposed on C- α ,C,N atoms of the well-defined region of Arc (residues 8–48 of each monomer)], backbone angular order parameters (averages from ϕ and ψ angular order parameters) [equation (35)], and $Q^{1/6}$ factors as a function of the residue sequence for the final Arc structures. Secondary structure elements in Arc are indicated. (The rmsd of the first four residues are off-scale and have values of up to 10 Å)

constraints are available. The structures, which have been deposited in the Brookhaven Protein Data Bank (entry 1ARR), have good stereochemical qualities and present an extensive pattern of hydrogen bonds and a good packing with a very well defined core.

6 CONCLUSION

The use of relaxation matrix calculations for the refinement of protein structures from NMR, as illustrated here for the Arc repressor, should result in a more accurate representation of the solution structure of a biomolecule. In addition, such methods also offer a tool to identify errors or overinterpretation in distance constraints and assess the quality of the NMR structures by a direct comparison of theoretical and experimental data. They should however not be used as single criteria for accuracy, but should be used together with others, such as the

stereochemical quality of the structure. An adequate description of motional effects like internal mobility (e.g. via order parameters, fast methyl group rotation, and aromatic ring flips) or conformational heterogeneity, allows a dynamic description of the structure in solution. A treatment of the experimental NMR data as time- and/or ensemble-averaged restraints should even lead us further toward a more realistic description of solution structures. Additional work is however required in this direction since the motional model is the most controversial point in the use of relaxation matrix calculations. The new developments both in software and hardware should extend the range of such computations to proteins of increasing size and allow the use of more detailed motional models for a better description of solution structure.

1 INTRODUCTION

Among the various techniques involved in the field of macromolecular structural determination, NMR spectroscopy has proven in the last decade to be a powerful tool for defining the folding of proteins,¹ as well as for structural studies of nucleic acid fragments in solution.² There is, however, a significant difference between the applications of NMR to the structural determinations of proteins and nucleic acids: while elucidation of the global secondary and tertiary structure of a protein still counts as a major achievement, for oligomeric nucleic acids this is a starting point rather than a goal. Secondary structures of nucleic acids (such as the helix type) are usually obvious from qualitative inspection of the NMR data (to the point that NMR studies of small duplexes has been qualified to be ‘as easy as A, B, Z’³), and tertiary structures are usually not exhibited by the small duplexes investigated so far. Hence NMR is used to determine the finer details of the structure of nucleic acids, such as small local variations of the puckering of the sugar moieties and of helical parameters.

2D NMR nuclear Overhauser effect spectroscopy (NOESY) experiments are usually the major sources of structural information by providing interproton distances. A difficulty arises from the fact that the nuclear Overhauser effect (NOE) develops by magnetization transfer through a network of dipoles (so-called spin diffusion), and depends on fluctuations in the position and the length of the interproton vectors due to the overall as well as to internal motions. Hence dynamics and structural information are embedded in NOE intensities, and need to be deconvoluted.

The approximation is often made that internal motions have negligible effects on magnetization transfers. Any unknown interproton distance r_{ij} is then calculated from a reference distance r_{kl} by comparing the cross-relaxation rates σ_{ij} and σ_{kl} according to

$$r_{ij}/r_{kl} = (\sigma_{kl}/\sigma_{ij})^{1/6} \quad (1)$$

In NMR studies of nucleic acids, two reference distances are preferentially used, namely, cytosine H-5–H-6 (248 pm) and deoxyribose H-2’–H-2’’ (179 pm). The cross-relaxation rates σ can be measured exactly as the initial NOE build-up rates. In

practice, however, an estimate of the initial slope is obtained by measuring the NOE intensity after a reasonably short mixing time, leading to the so-called two-spin approximation, and NOEs rather than cross-relaxation rates σ are used in equation (1). Distances obtained from equation (1) have proven to be useful in determining the global folding of a protein, in which case the accuracy with which the distances are known is not crucial: in the structural reconstruction process, distances are only provided as upper and lower bounds, which are meant to include all possible misinterpretations. For example, weak NOEs are associated with uncertainties to account for large distances in relatively rigid regions or for short distances in very mobile regions. However, analysis of finer structural elements, such as those considered for nucleic acid fragments, cannot rely solely on this type of estimated distances, for several reasons. First, many of the structurally useful NOEs are not observed at short mixing times (e.g., H-1’ and H-3’ to H-8,6). In the case of long linear molecules, such as the DNA fragments studied so far, this could lead to erroneous patterns such as curved DNA through accumulation of errors.² Second, the two-spin approximation has been shown to yield incorrect estimates of distances.^{2,4–8} Because of diffusion via H-2’, for instance, the H-3’ and the H-2’’ are placed with respect to H-8,6 with an error amounting to more than 100 pm. Both distances, however, are essential to position the sugar moieties in DNA with respect to their bases. An illustration of the spin diffusion pathways in DNA is shown in Figure 1. Third, local motions, which play an important role in relaxation phenomena, have been shown to be important in nucleic acids, yielding, for example, different correlation times for sugar and bases.^{9–11} equation (1) limits the interpretation of the relaxation data to structural information, discarding the dynamics of the molecule, which is known to play an important role with respect to its function.¹²

To overcome the above-mentioned problems, inherent to equation (1), several approaches that include the longitudinal relaxation of the whole spin system^{4,6–8,13–20} have been suggested, mainly to compensate for spin diffusion effects, with some attempts to include dynamics. They all have in common that the full relaxation rate matrix **R** is calculated by solving the set of generalized Bloch equations (the full relaxation matrix is, in fact, a subset of the whole Redfield matrix, since it concerns only the relaxation of the longitudinal

Figure 1 Stereoview of the trinucleotide d(CGC). Standard B-DNA geometry has been assumed. All interproton vectors whose norm is shorter than 400 pm are shown as dashed lines, illustrating the spin diffusion pathways

magnetization; ‘full’ refers to the fact that the complete spin system is included in the calculation). These methods, which were first developed for the analysis of NMR data of nucleic acids, have now been applied to proteins (see *Protein Structures: Relaxation Matrix Refinement*). In order to understand the basis of these methods, we shall first summarize the elements of the relaxation theory that are of importance for the interpretation of NOE data; then we shall present a brief description of the different relaxation matrix refinement techniques.

2 RELAXATION MATRIX AND NOE INTENSITIES

Under the assumption that cross correlation can be neglected, Kalk and Berendsen²¹ have derived the so-called generalized Bloch equations, which govern the time dependence of the magnetization M_{zi} of each spin i within the molecule of interest. These sets of coupled differential equations can conveniently be expressed in matrix notation as²²

$$\frac{d}{dt} \begin{bmatrix} M_1 \\ M_2 \\ \vdots \\ M_n \end{bmatrix} = - \begin{bmatrix} \rho_1 & \sigma_{12} & \dots & \sigma_{1n} \\ \sigma_{21} & \rho_2 & \dots & \sigma_{2n} \\ \vdots & \vdots & \ddots & \vdots \\ \sigma_{n1} & \sigma_{n2} & \dots & \rho_n \end{bmatrix} \begin{bmatrix} M_1 \\ M_2 \\ \vdots \\ M_n \end{bmatrix} \quad (2)$$

with $M_i = M_{zi} - M_{zi0}$. Here M_{zi0} is the z magnetization of spin i at equilibrium, ρ_i is the auto (longitudinal) relaxation rate of spin i , and σ_{ij} is the cross-relaxation rate between spin i and spin j . Assuming that relaxation mechanisms are dominated by dipolar interactions, the relaxation rates ρ_i and σ_{ij} for homonuclear proton relaxation in solution are given by

$$\rho_i = \alpha \sum_{j \neq i} [J_{ij}(0) + 3J_{ij}(\omega) + 6J_{ij}(2\omega)] \quad (3)$$

$$\sigma_{ij} = \alpha [6J_{ij}(2\omega) - J_{ij}(0)] \quad (4)$$

where α is a constant that depends on the gyromagnetic ratio of the nucleus (for protons, $\alpha = 5.69 \times 10^{-41} \text{ s}^{-2} \text{ m}^6$). The variable ω is the Larmor frequency of the proton, and $J_{ij}(\omega)$ are the spectral density functions, obtained as the cosine Fourier transforms of the time correlation functions, defined by (in the laboratory frame)

$$C_{ij}(t) = \left\langle \frac{P_2(\boldsymbol{\mu}(t) \cdot \boldsymbol{\mu}(0))}{r_{ij}^3(t)r_{ij}^3(0)} \right\rangle \quad (5)$$

where r_{ij} is the interproton distance between i and j , and $\boldsymbol{\mu}$ is a unit vector pointing from i to j . P_2 is the second-order Legendre polynomial defined by $P_2(x) = \frac{1}{2}(3x^2 - 1)$. If all the interproton vectors are assumed to be rigid and to move isotropically, the spectral density function takes the form

$$J_{ij}(\omega) = \frac{1}{r_{ij}^6} \frac{\tau_c}{1 + (\omega\tau_c)^2} \quad (6)$$

where τ_c is the overall rotation correlation time.

Equation (2) can be rewritten as

$$\frac{d}{dt} \mathbf{M} = -\mathbf{R}\mathbf{M} \quad (7)$$

where $\mathbf{R}$ is the relaxation rate matrix. The solution of the set of generalized Bloch equations is then

$$\mathbf{M}(\tau_m) = \exp(-\mathbf{R}\tau_m)\mathbf{M}(0) \quad (8)$$

These equations can be generalized for the analysis of 2D NOESY spectra,²² in which case $\mathbf{M}(\tau_m)$ is a matrix proportional to the normalized NOE intensities recorded with a mixing time τ_m , and $\mathbf{M}(0)$ is the diagonal matrix containing the equilibrium z magnetization.

3 RELAXATION MATRIX REFINEMENT

As can be seen from equations (3)–(5) and (8), extracting structural and dynamical information from NOE intensities first requires generation of the relaxation matrix. The ideal and most direct way to calculate $\mathbf{R}$ is to take the logarithm¹⁴ of equation (8), yielding

$$\mathbf{R} = -\frac{1}{\tau_m} \ln[\mathbf{M}(\tau_m)\mathbf{M}(0)^{-1}] \quad (9)$$

This approach, however, requires that all NOE intensities be quantified; this condition will generally not be fulfilled owing to experimental limitations such as poor signal-to-noise ratios in the case of weak peaks and of peak overlaps, which in the case of DNA fragments are usually severe on the diagonal and in all regions concerning H-2'–H-2''. Even in the presence of small overlaps, this direct method was found not to be reliable for DNA studies.²³

An alternative approach consists in testing model structures for the molecule of interest. The relaxation matrix of a given model structure can be calculated by assuming a particular model for the spectral density functions, from which NOE intensities are computed based on equation (8). These calculated values are then compared with the experimental NOE intensities, and the model structure that provides the best agreement is selected. The success of this trial-and-error approach is limited by the ability to generate appropriate trial structures.

Attention has been focused on improving both routes in order to circumvent their drawbacks, yielding two distinct sets of relaxation matrix refinement procedures.

3.1 Deriving the Relaxation Matrix from an Incomplete Set of NOE Data

A systematic search that compares the experimental NOE intensities with calculated values obtained for all possible conformations of the molecule would directly yield the family of structures compatible with the data. At the present state of computer technology, however, this strategy is computationally prohibitive, even for short DNA fragments of six base pairs. One route to circumvent this computing

Figure 2 Flowchart of the methods of reconstruction of the relaxation matrix from an incomplete set of NOE intensities

limitation is to refine automatically the structure based on the available NOE intensities. A general flowchart of this approach is shown in Figure 2.

The goal of this method is to optimize iteratively a trial structure while minimizing the error χ^2 between the calculated and observed intensities:

$$\chi^2 = \sum_{i,j} \left[\frac{\text{NOE}_{\text{obs}}(i,j) - \text{NOE}_{\text{calc}}(i,j)}{\sigma(i,j)} \right]^2 \quad (10)$$

where $\text{NOE}_{\text{obs}}(i,j)$ and $\text{NOE}_{\text{calc}}(i,j)$ are the observed and calculated NOEs for the pair of protons i and j , and $\sigma(i,j)$ is the standard deviation of that NOE estimated from the signal-to-noise ratio on the NOE spectrum. The full procedure comprises the following.

1. **Initial Model** For DNA, a reasonable starting structure is assumed, such as right-handed B DNA, especially if there is independent evidence of the nature of the gross structure (see *Nucleic Acids: Spectra, Structures, and Dynamics* and *DNA: A-, B-, and Z-*).
2. **NOE Calculation** Based on this initial model, the relaxation matrix is calculated from equations (3) and (4), usually assuming the spectral density functions to be of the form described by equation (6). NOE values are then calculated either by numerical integration of the generalized Bloch equations, equation (2),^{6,15} or directly from equation (8), which first requires the relaxation matrix to be diagonalized: $\mathbf{R} = \mathbf{P} \mathbf{D} \mathbf{P}^{-1}$. Then

$$\mathbf{M}(\tau_m) = \mathbf{P} \exp(-\mathbf{D} \tau_m) \mathbf{P}^{-1} \mathbf{M}(0) \quad (11)$$

3. **Structural Parameters to be Determined** Structural parameters of DNA molecules are commonly reported as torsion angles. The glycosidic torsion angle χ and the sugar pucker parameters P and θ_{max} describe the structure of each nucleotide. The helical twist θ_t , the base pair roll θ_r , the propeller twist θ_p , and the base pair tilt t give the orientation of the bases with respect to one another. The helix

displacement D and the local rise h describe the relative position of the helix axis and the vertical translation of each base pair. Methods of refinement based on the torsion angles usually do not include torsion angles in which phosphates are involved, since these angles are known to be subject to more extensive motional averaging than the rest of the molecule.^{24,25} The main advantage of using torsion angles as variables compared with Cartesian coordinates resides in a significative reduction of the number of parameters, since all bond lengths and angles remain constant. Cartesian coordinates, however, have not been discarded, since they allow analytical calculations of the derivatives of the residual χ^2 , as well as direct coupling with other techniques such as molecular dynamics (MD). This will be described below. Finally, distances themselves can be used as variables.

4. **Updating the Structural Parameters** In the torsion angle space, variables are modified according to the gradients of the residual χ^2 ; these gradients have so far been calculated only numerically for nucleic acids (analytical derivatives exist in the case of proteins²⁶). A new trial structure is calculated from these new parameters. The procedure is iterated until convergence is achieved (i.e., there is negligible variation of χ^2 between two steps). The principle of this approach has been described in detail by Lefèvre et al.⁶ and Borgias and James;²³ the latter have given the acronym COMATOSE to their program.

In principle, a similar procedure could be derived in Cartesian coordinate space, with the requirement that additional constraints be included to maintain the stereochemistry of the molecule. Though this approach would further benefit from analytical expressions for the gradients of the residual,²⁷ it has not yet been applied as such for structural refinement of nucleic acids. Alternative approaches have been proposed in which distances rather than Cartesian coordinates are updated, based on the relation

$$r_{ij}(\text{new}) = r_{ij}(\text{old}) \left[\frac{\text{NOE}_{\text{calc}}(i,j)}{\text{NOE}_{\text{obs}}(i,j)} \right]^{1/6} \quad (12)$$

These distances can then be used to refine the positions of the protons directly, without consideration of the other atoms (program NO2DI²⁸). The full molecule is built at the end of the iteration scheme. Another possibility is to include these distances in molecular mechanics or molecular dynamics calculations in order to derive a new reasonable trial structure, which is then used to derive the new set of calculated NOEs.²⁰

All the methods presented above depend strongly on the model chosen for the internal dynamics of the molecule in order to calculate the relaxation matrix from its structure. An alternative approach is to use a least-squares optimization to fit the appropriate terms in the relaxation matrix directly to the experimental NOEs. The main point of this method is that it first handles the problem of spin diffusion rigorously, before getting to the details of the determination of the structure and dynamics of the molecule; these features are derived from the direct analysis of the relaxation rates ρ and σ . This method was reported to be successful for relatively small cross-relaxation networks involving subsets of the protons of a DNA molecule.^{29,30}

Figure 3 Flowchart of the hybrid matrix approach

3.2 Deriving the Relaxation Matrix from a Hybrid Set of Calculated and Observed NOE Intensities

The second route to circumvent the problem of missing NOE intensities is the so-called 'hybrid matrix approach',^{16,17,31} illustrated in Figure 3. The hybrid matrix approach proceeds as follows. First, NOE values are calculated from a model structure, usually via equation (8). Next, after scaling the calculated NOE intensities to the experimental values, the NOEs for which measured values are available are substituted into the NOE matrix leaving the rest unchanged. Thus, a hybrid NOE matrix is constructed, which is complete and can therefore be used to back-calculate the relaxation matrix via equation (9). Distances are subsequently extracted from this matrix, assuming a model for the dynamics of the molecule. In the IRMA approach,^{16,17} this set of refined distances is used immediately to refine the model, using restrained molecular dynamics calculations. This updated structure serves as a new trial structure for the next cycle. In the MARDIGRAS approach,³¹ the updated set of distances is used again to calculate a 'model' NOE matrix for the next cycle. Iterations are pursued until good agreement is obtained between the model and the observed NOE values, measured, for example, through a residual [equation (10)]. In the MARDIGRAS approach, only relaxation rates that have a corresponding observed NOE are allowed to change. Both methods allow the incorporation of NOE data at several mixing times. Hybrid NOE matrices are then calculated for each mixing time, and the resulting relaxation matrices are averaged to yield the relaxation matrix used to estimate the distances.

Calculation of the relaxation matrix from the full NOE matrix based on equation (9) requires that all eigenvalues of the matrix $\text{NOE}(\tau_m)[\text{NOE}(0)]^{-1}$ be positive. This may not be the case when the hybrid NOE matrix is used. If a negative eigenvalue appears, either the corresponding mixing time is discarded or the eigenvalues are shifted so that all become positive.³¹

4 IMPROVEMENTS

The full relaxation matrix approaches have been shown to yield more reliable sets of distance constraints than can be obtained by the conventional initial rate analysis.^{6,16,17,31} The effect of spin diffusion is taken into account in an accurate way either by solving the Bloch equations (Section 3.1) or by back-transformation of a hybrid calculated/experimental NOE matrix (Section 3.2). Application of these techniques, however, requires the quantification of a large number of NOEs, the definition of a model for the dynamics of the molecule, and a criterion for assessing the final model structures. These issues will be discussed below.

4.1 Quantification of NOE Data

Quantification of NMR experimental data is a crucial problem that is not specific to relaxation matrix refinements. A priori, because of the r^{-6} dependence, no great accuracy in the determination of the cross-relaxation rates is required; for example, an error of a factor of 2 in σ results in an error of about 10% in r . However, the situation is worse if one tries to extract dynamical information from the cross-relaxation rates, which depend linearly on the correlation times. Also, in cases where enough NOEs are available to constrain the molecule, good convergence toward a correct model can be expected. In cases in which the NOE data set is very incomplete, the convergence will become strongly dependent on the initial structure. Quantification usually proceeds through peak picking and numerical integration over a box containing the isolated cross peak of interest, or by a nonlinear least-squares fit in the frequency domain in the presence of overlap. Limitations of these procedures appear, however, for low signal-to-noise ratio, as well as in crowded or complicated spectra that show severe overlaps. In these cases, alternative approaches that have attracted considerable interest recently are linear prediction (LP)³² and maximum entropy³³ methods, though no direct applications have yet been proposed.

4.2 Influence of the Dynamics of the Molecule

Spin diffusion affects the interpretation of experimental data in terms of relaxation rates, while dynamics affects the interpretation of the relaxation rates in terms of structural parameters. Most of the full relaxation matrix approaches presented above combine these two problems in order to derive the structure of the molecule directly from experimental data. It is worth mentioning that the effects of spin diffusion and dynamics can be separated in the process of analyzing NOE data,^{29,30} though a model for the dynamics is still required in order to derive the structure of the molecule of interest. In the latter approach, however, information on the dynamics can be obtained from cross-relaxation rates involving protons separated by fixed distances, such as H-2'-H-2'' and H-5-H-6.²⁹

In the calculation of the relaxation matrix from a known model structure, the molecule is usually assumed to be a rigid body undergoing only overall motion with a single correlation time τ_c . Under this assumption, the spectral density functions are described by equation (6). However, internal motions

induce changes in the cross-relaxation rates. Several methods have been suggested to incorporate the effect of local motion in the interpretation of NOE data for DNA molecules. In the case of the two-spin approximation, three different correlation times were chosen:³⁴

1. one for the sugar–sugar, base–base, and sugar–base cross peaks not involving H-2', H-2'', and methyl groups;
2. one for all the cross peaks involving H-2' and H-2'';
3. one for cross peaks involving methyl groups.

In the case of full relaxation matrix calculations, a better fit to the NOE data could be obtained when small variations in the overall correlation time were allowed,³⁵ or when extra effective correlation times were added for the interproton vectors to H-2' and H-2'', to account for possible anisotropy of the overall motion of the molecule,²⁰ related to the fact that DNA molecules are better represented by cylinders than by spheres. A protocol for the incorporation of these internal motions directly in the refinement of the relaxation matrix was also proposed.³⁶ In this method, systems where overall and fast internal motions occur are described by the model-free approach proposed by Lipari and Szabo.³⁷ This approach describes systems with three different parameters, namely, the overall correlation time τ_c , a generic correlation time τ_i to describe the rate of all fast internal motions, and a generalized order parameter S^2 . S^2 varies between 0 for complete isotropic motion and 1 in the absence of local motion. The time correlation functions, equation (5), are rewritten in the form

$$C_{ij}(t) = S^2 \langle r_{ij}^{-6} \rangle \exp\left(-\frac{t}{\tau_c}\right) + (1 - S^2) \langle r_{ij}^{-6} \rangle \exp\left(-\frac{t}{\tau_e}\right) \quad (13)$$

where $\tau_e^{-1} = \tau_c^{-1} + \tau_i^{-1}$. The spectral density function is then given by

$$J_{ij}(\omega) = S^2 \langle r_{ij}^{-6} \rangle \frac{\tau_c}{1 + (\omega\tau_c)^2} + (1 - S^2) \langle r_{ij}^{-6} \rangle \frac{\tau_e}{1 + (\omega\tau_e)^2} \quad (14)$$

If the internal motions are in the motional narrowing limit ($\omega\tau_e \ll 1$) and are very fast compared with the overall motion ($\tau_i \ll \tau_c$), the second term in equation (14) can be neglected, yielding

$$J_{ij}(\omega) = S^2 \langle r_{ij}^{-6} \rangle \frac{\tau_c}{1 + (\omega\tau_c)^2} \quad (15)$$

Equation (15) is used instead of equation (6) to calculate the relaxation rates. In the absence of experimental values, both S^2 and $\langle r_{ij}^{-6} \rangle$ can be obtained from molecular dynamics simulations. The modified relaxation matrix refinement that uses this description of the internal dynamics consists in

1. determination of a first approximate structure based on an hybrid relaxation matrix approach, without inclusion of the fast internal motions;
2. free MD simulation in order to extract the generalized order parameters as well as the average distances;
3. a few more cycles of relaxation matrix refinement with inclusion of motion for further structure refinement.

Progress in this direction is expected, since the recent possibility of synthesizing ¹³C-enriched nucleic acid fragments at a reasonable cost will help in extracting experimental values for the generalized order parameters.

4.3 Assessment of the Refined Structure

The common procedure to judge the quality of the final structure is a direct comparison of the theoretical and experimental NOE intensities, either by means of a residual χ^2 , equation (10), or, for direct comparison with X-ray crystallography, by using the R factor defined by Gonzalez et al.:³⁸

$$R = \frac{\sum_{i,j} |\text{NOE}_{\text{obs}}(i, j) - \text{NOE}_{\text{calc}}(i, j)|}{\sum_{i,j} \text{NOE}_{\text{obs}}(i, j)} \quad (16)$$

where the summation extends over all measured cross peaks i, j . However, neither the χ^2 residual nor the R factor include information on peaks whose intensities were too small to be detected, or on peaks that could not be quantified because of severe overlaps.

Another way of assessing the final structure is by simulation of the NOESY spectrum based on the calculated NOE intensities, and visual comparison of both simulated and experimental spectra. This procedure, which does not suffer the same drawbacks as the use of its R factor, has now been included in interactive relaxation matrix refinement procedures.^{18,36,39}
